LIST OF CONTRIBUTORS TO VOL. XLVIII.

Abrahams, Dr. R., New York.
Allen, Dr. Charles W., New York.
Allport, Dr. F., Minneapolis, Minn.
Ames, Dr. F. H. S., Denver, Col.
Andrews, Dr. A. J., Brooklyn, N. Y.
Ashmead, Dr. Albert S., New York.
Ayers, Dr. Edward A , New York.

Babcock, Dr. R. H., Chicago, Ill.
Bailey, Dr. Pearce, New York.
Baldwin, Dr. E. R., Saranac Lake, N. Y.
Bannan, Dr. T., Syracuse, N. Y.
Barkan, Dr. Louis, Brooklyn, N. Y.
Barney, Dr. Joseph N., Jr., Woodstock, Va.
Baruch, Dr. Simon, New York.
Bashore, Dr. H. B., Fairview, Pa.
Bates, Dr. W. H., New York.
Baylies, Dr. E. B., Dayton, O.
Beatly, Dr. W. Kirker, Long Island City, N. Y.
Bell, Dr. J. N., Detroit, Mich.
Bennett, Dr. C. L., Agues Calientes, Mexico.
Berry, Dr. William B., Passadena, Cal.
Bissell, Dr. J. Dougal, New York.
Blackford, Dr. C. M., Lynchburg, Va.
Blech, Dr. Gustavus, Detroit, Mich.
Bleyer, Dr. J. Mount New York.
Booth, Dr. J. Arthur, New York.
Boteler, Dr. W. C., Kansas City, Kan.
Bowerman, Dr. A. C., Pictou, Ontario.
Bradshaw, Dr. J. H., Orange, N. J.
Breen, Dr. A. E., Rochester, N. Y.
Bremer, Dr. Ludwig, St. Louis, Mo.
Brendon, Dr. E. V., New York.
Brown, Dr. J. S., Montclair, N. J.
Buchanan, Dr. J. J., Pittsburg, Pa.
Buck, Dr. Albert H., New York.
Bulkley, Dr. L. D., New York.
Bullard, Dr. William L., Columbus, Ga.
Burrall, Dr. F. A., New York.

Cabot, Dr. John, New York.
Cadwallader, Dr. R., Fall River Mills, Cal.
Chapin, Dr. H. D., New York.
Cheesman, Dr. Hobart, New York.
Cole, Dr. Carter S., New York.
Cole, Dr. W. F., Waco, Tex.
Coleman, Dr. Warren, New York.

THE IMPORTANCE OF ADMINISTERING IODIDE OF POTASSIUM IN LARYNGEAL DISEASES OF DOUBTFUL DIAGNOSIS.[1]

BY CLARENCE C. RICE, M.D.,

PROFESSOR OF DISEASES OF THE NOSE AND THROAT, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

THE clinical value of this paper might be largely increased by making this change in its title: "The Importance of Administering Iodide of Potassium in Many Cases of Laryngeal Disease which Apparently are Non-syphilitic."

Any suggestion as to the advisability of prescribing the iodide will of course be superfluous to those clinicians who are in the habit of diagnosing almost all cases of inflammation of the upper air-passages as syphilitic. We know that there are physicians of this frame of mind. On the other hand, we are satisfied that there are many who do not resort to the administration of mercury and potassium unless they are convinced that the lesion under treatment is specific. They desire conclusive evidence, and it is possible that they frequently are in error in withholding specific treatment because of lack of marked diagnostic points. Further, even expert laryngologists may easily fall into the habit of quickly classifying all laryngeal lesions in an instinctive way, and if the first impression is that the disease is other than specific it will not occur to them to use the iodide, even though the case is not progressing favorably.

It has always been my habit of thought to be slow in believing a lesion was specific, unless the history strongly indicated it, or unless the lesion presented such an appearance in a clear manner. The more experience we obtain in clinical work, however, the more, I believe, we appreciate how small is the percentage of cases which closely present the characteristic appearances portrayed in the text-books. Authors are not to be blamed for describing pathological appearances as typical and constant, for, should they endeavor to mention the many great and small variations of behavior from the typical aspects, their work would not only be too voluminous, but so confusing that the beginner in laryngology would have no salient points on which to found his diagnosis.

I was much impressed in listening to a discussion[2] on "Unusual Manifestations of Tuberculosis," by the American Laryngological Association a few years ago. One after another, men who had been active in laryngology for twenty-five years or more put themselves on record as frequently being unable to make a diagnosis of laryngeal inflammation or neoplasm, from the physical aspect of the lesion, together with the clinical history. They confessed that they were often compelled to withhold their opinion until more examinations had been made, until the microscope had aided them, or the effect of the iodide had been demonstrated.

One of the most prominent laryngologists of this city remarked, in this same discussion, that there was such a thing as "diagnostic instinct;" and he meant that this had sometimes to be depended upon when all the other signs failed.

It cannot be denied that, there are many cases of laryngeal disease which are difficult of diagnosis, and a number where it is impossible to state positively, for a time at least, the nature of the disease.

We might commence by saying that we have a belief, founded on some experience, that there are cases of laryngeal disease non-specific, which are benefited to some degree by the administration of small doses of iodide of potassium. Perhaps the beneficial action obtained in these cases is essentially by reason of its so-called alterative effect, and would not be gained if the drug was administered in large doses, or if it was continued for any length of time. I have frequently noticed this effect of the iodide. The benefit from five grains three times a day was immediate and remarkable, and that, too, after diligent treatment had been pursued along other lines.

We find a number of writers who state that they have obtained the same beneficial result from iodide when given in the early stages of laryngeal tuberculosis and in chronic laryngitis.

I shall mention these farther on.

It seems to me that the habit of administering the iodide depends largely upon the amount of dispensary work one may be engaged in. Certainly there was no need of advising its use in Charity Hospital in the 80's. I often wonder what became of the remarkable cases of syphilis of the larynx which were in the hospital at that time, cases in which the epiglottis had been entirely destroyed, others in which the entire laryngeal mucous membrane had been replaced by cicatricial tissue and the whole cavity distorted, and those in which the vocal bands were adherent to each other through the medium of webbed formations. I personally see few of such patients at the present day. I dare say this decrease in cases of such extensive lesions is due to the better and more intelligent treatment which patients now receive. The attention which is paid to the cleanliness of the nose and pharynx would diminish very much the likelihood of such severe syphilitic lesions. Patients, too, are more often seen at an earlier stage of the disease than they were fifteen years ago.

There is not time here to mention the characteristic diagnostic points of each of the many diseases of the larynx. The typical lesions of each laryngeal disease we are all familiar with, and when present they furnish readily the means of diagnosis, but we often see ulcerations characteristic of no special process, but which might be the result of several, and we find enlargements or neoplasms about which no intelligent opinion can be at first formed. There are several laryngeal diseases other than syphilis which frequently present, during some part of their development, pathological conditions which in general aspect are quite similar to syphilitic lesions, and it is in these cases we would advise the administration of iodide of potassium for a time, even though there is strong belief that the disease is not syphilis.

First let us say a few words in regard to laryngeal tuberculosis. In the typical cases one would hardly be tempted to prescribe the iodides, but there are many

[1] Read before the Laryngological Section of the New York Academy of Medicine, May 22, 1895.

[2] Rice: Unusual Manifestations of Tuberculosis of Larynx, Transactions of the American Laryngological Association, 1889, p. 95.

which are not so easy of diagnosis unless we find the bacilli and are satisfied that their presence is conclusive. If we find the characteristic epiglottis, club-shaped arytenoids, the general anæmia, and the superficial gray ulcerations, we cannot of course be in doubt, but there are many cases of tubercular ulceration which I am satisfied are complicated by the coexistence of a syphilitic process.

In 1889, I cited a case[1] (Fig. 1) under the title of "Unusual Manifestations of Tuberculosis," in which,

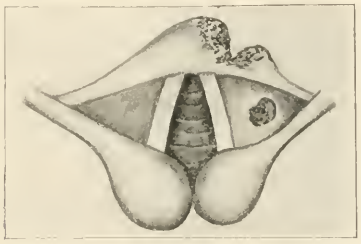

Fig. 1.—Coexistence of Laryngeal Syphilis and Tuberculosis.

in addition to apparently typical tubercular ulcerations in the larynx, there was extensive loss of tissue of the epiglottis. The ulceration of the epiglottis was out of proportion to the progress of the ulceration in the larynx. The arytenoids were characteristically tubercular. The patient had advanced pulmonary involvement, but in spite of this the ulceration on the epiglottis was healed by the use of iodide of potassium, although it had no effect whatever upon the intralaryngeal tubercular ulcerations. I think it possible that the coexistence of these two diseases is more frequent than we are apt to believe. There is no doubt that patients often contract syphilis early in life and tuberculosis later. Many of the cures of laryngeal tuberculosis which we see in print are probably syphilitic. If we have any doubt as to the character of an ulceration it should have the benefit of the iodide.

Is it not possible that a patient may have at the same time pulmonary tuberculosis and syphilis of the larynx? We see cases of ulceration of the larynx in patients having pulmonary tuberculosis with tubercle bacilli in the sputa, which are healed by the iodide.

Dr. Woodward, of Burlington, Vt.,[2] a laryngologist of experience, reports two cases of laryngeal ulceration in both of which tubercle bacilli were found, and the lungs showed evidences of tuberculosis. In both cases the laryngeal ulcerations were healed by iodides. He believes the cases to have been syphilitic.

Dr. F. I. Knight, of Boston, in discussing the paper on the "Unusual Manifestations of Tuberculosis of the Larynx," remarked that in some cases where he had been sure enough of the presence of tubercular disease of the larynx to allow the patient to go without constitutional treatment, he had been happily disappointed to see the ulcerations disappear under specific treatment.

Dr. Jonathan Wright,[3] in a paper, said that two cases of tracheal and one of laryngeal disease had been referred to him. They both had marked pulmonary signs. The thickening was so great that tracheotomy was performed, I believe, in both cases. An unquestioned diagnosis of tubercular laryngitis was made. They died some time after the tracheotomies. The autopsies demonstrated syphilis of the larynx.

It is a good diagnostic point that tuberculosis of the larynx seldom produces occlusion enough to necessitate tracheotomy.

Cases which might be tubercular or syphilitic, so far as the physical aspect of the laryngeal lesions are concerned, are those in which, neither the epiglottis or arytenoids being involved, a single ulceration presents itself on the vocal band or upon the side of the larynx, with no qualities whereby its character may easily be determined. Of course, we depend here upon the presence of lung disease and of bacilli, but even if they are both found the ulceration of the larynx may be syphilitic.

Almost all the diseases of the larynx which go through an ulcerative stage are capable of producing so-called granulation tissue upon the surface of the ulceration. We have the "vegetative" form of tuberculosis, and the granular thickening of the vocal bands in trachoma. Benign neoplasms of the vocal bands may present nearly the same appearances at times as the condylomata of secondary syphilis, and the wart-like excrescences of the tertiary stage. All of these conditions look much alike, and at times it will be difficult to exclude syphilis. It will be wise to see if they are benefited by the administration of the iodide.

There is considerable confusion as to the identity of the pathological conditions known by some as "chorditis tuberosa;" by others as "singers' nodes," and by others as "trachoma vocalis." Bosworth[1] and Ingals[2] think "chorditis tuberosa" and trachoma are the same thing. F. I. Knight[3] says they may be the same pathologically, but that they differ in clinical behavior. John Mackenzie says we should distinguish between a granular condition of the vocal bands and true "chorditis tuberosa." But the point which is most pertinent to this paper is that these processes of hypertrophy of the vocal bands often present appearances which closely simulate syphilitic lesions, and, therefore, clearly indicate the treatment.

Ingals,[4] in his text-book, gives an illustration of a thickening in a simple catarrhal laryngitis, which is formidable enough to be a syphilitic enlargement.

John Mackenzie speaks of "hypertrophic laryngitis," and says that it is with difficulty diagnosed from syphilis.

We frequently see changes in the vocal bands in simple catarrhal processes, in which we are tempted to use the iodide.

I will cite a case in which the lesions were almost entirely confined to the vocal bands, because of its unusual behavior and because of the effect of iodide upon it.

Case.—Male, aged fifty-five. First saw him in September, 1894. Patient was hoarse, and consequently much troubled because he was a school-teacher. General condition good. No syphilitic history, and no lesion in other parts of the body to indicate that he had ever had disease of this nature. Growth the size of two large peas attached to right vocal band posterior third. Band itself slightly congested, but not markedly so. Growth was removed and examined in the laboratory of the Post-Graduate Hospital, and pronounced a simple papillomatous growth. (Fig. 2.) When next the patient was seen, a few weeks later, I found that the entire vocal band was thickened, reddened, and granular, in the sense of being very uneven. There were no ulcerations, but the band presented a very ragged appearance. Astringent applications were made. Later, growth somewhat similar to the first one, well localized, but smaller, appeared on the opposite chord, and after a few weeks that vocal band became generally thickened and congested. At one time it looked as if the inflammatory process would extend to the side of the larynx, but that was probably due to the operative work. The

projections were removed by forceps and guillotine wherever they were large enough to be taken hold of, and several times the galvano-cautery was used. The larynx behaved very well after operation, and the subsequent inflammation was moderate. Not much improvement of the voice was obtained, because of the great amount of general thickening of the vocal chords. (Fig. 3.) Patient was put upon iodide of potassium in small doses and the larynx commenced to improve at once. The warty excrescences became smaller day by day and the congestion and general thickening diminished. The case at first was naturally supposed to be one of simple papilloma of the larynx, but the rapid involvement of the entire vocal bands later on pointed toward epithelioma. The appearance of the bands after they became thickened and jagged was very similar to trachoma vocalis. The effect of the iodide upon this case was so remarkable that we shall perhaps be compelled to call it a syphilitic process. The patient

Fig. 2.—Syphilitic inflammatory growth of vocal band.

Fig. 3.—Syphilitic hypertrophy of the vocal bands.

never took more than ten grains of the iodide three times a day. A polypus was removed from left nostril.

Some of the reasons why we cannot always decide easily whether a pathological condition is syphilitic or not, are, that it is very frequently impossible to obtain any corroborative history. The patient has had some venereal disease, but there are no evidences of syphilis elsewhere. Of course, where the scars of old inflammations are found in the nose or pharynx, the diagnosis is made. We have already mentioned that the tertiary manifestations, which are by far the most common in the larynx, are frequently obscured by a coexisting tubercular process. The primary sore of syphilis most of us will probably never see in the larynx, and very rarely shall we be called upon to diagnose mucous patches. Secondary ulcerations of the larynx are usually accompanied with a clear recent history, and syphilitic manifestations of the mouth. Congestions or erythemas due to syphilis have some distinguishing signs, and are most apt to be accompanied by the same pathological conditions of the pharynx.

The tertiary lesions of syphilis, growths, gummata, and extensive ulcerations, are attended by more difficulties of diagnosis. Almost always the gummatous enlargements have undergone ulceration by the time they reach us, so that we have to deal with ulcerations of most varied appearances in the larynx. If such ulcerations occur, as they very frequently do, in patients much debilitated and generally anæmic, they present conditions which are but slightly, if at all, different from those of tuberculosis. If we cannot obtain a syphilitic history, or find specific lesions in the pharynx, or other parts of the body, then it will be necessary to exclude tuberculosis.

Now, in regard to perichondrial inflammation of the laryngeal cartilages. We know that as a primary disease it exists very rarely, but is on the other hand an indication of tuberculosis or syphilis. In 33 cases tabulated by Bosworth,[1] 9 were syphilitic and about the same number followed typhoid fever. The tubercular cases were not included in this list.

Several authors agree that when the arytenoids are attacked by perichondrial inflammation the strong inference is that the process is tubercular, because the other inflammatory diseases seem to prefer the cricoid and thyroid.

Bilateral enlargements of the arytenoids present no special interest, and may usually be put down at once as being tubercular, and we occasionally see marked enlargement of one arytenoid with anchylosis at the joint, in which all the phases of tubercular laryngitis rapidly follow. I cite the following case: First, because it was supposed to be tubercular; second, because there were reasons why an acquired syphilitic condition was not supposed possible; and third, to note the effect of iodide upon it.

Case.—Male, about forty years of age, works in an office. Very small, weighing, I should think, about ninety pounds. Heredity good. Chronic conjunctivitis, granular lids, decided scrofulous appearance. Slight cough for a year. Husky voice. Rough and high-pitched breathing at apices. Tubercle bacilli, very few found in expectoration. Laryngeal appearance as follows: Left vocal band immovable, markedly congested throughout its entire length and thickened. Marked enlargement of left arytenoid cartilage. Positively asserted that there was no specific history. Patient asserted that he had never had intercourse with women, and his statement seemed probable as his genital organs were very much undeveloped; his penis was no larger than a child's five years of age. Diagnosis at first thought to be tubercular perichondritis, although the uniform redness of the vocal band without ulceration did not seem like a tubercular lesion. (Fig. 4.)

I need not enlarge upon this case, except to say that the patient was not improved by ordinary laryngeal medications, nor by cod-liver oil and tonics. Iodide was commenced in small doses and the benefit was immediate, and after three weeks of its administration, in ten-drop doses, the enlargement of the arytenoid had almost entirely disappeared, the vocal band moved, and its congestion was so decreased that the voice was almost entirely restored. Before treatment the swelling

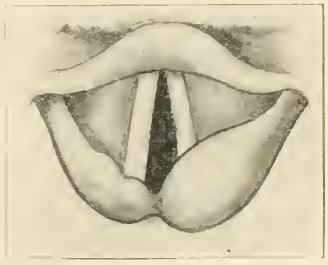

Fig. 4.—Syphilitic perichondritis.

[1] Bosworth: Diseases of the Throat, p. 565.

of the arytenoid was so great that there was some dyspnœa and he was unable to swallow solid food. I have never seen the effect of the iodide more marked than in this case.

Bosworth says that the iodide is useful in perichondritis, whether it is syphilitic or not.

We have spoken of the ulcerative lesions of the larynx, and of the confusion which may attend their diagnosis, and also of the tissue hypertrophies which are caused by a number of different inflammatory processes.

It remains to allude briefly to the growths or neoplasms of the larynx, benign and malignant, and to note their similarity to syphilitic lesions, and the difficulty oftentimes in their earlier stages of diagnosing them, and consequently the advisability of administering iodide until the diagnosis is confirmed by microscopical examination.

In our first case we referred to a supposed simple papilloma of the vocal band, the base of which was absorbed by the action of iodide.

Before speaking in detail of growths in the larynx of whatever nature, I cannot help alluding to a review, by Dr. Jonathan Wright,[1] of a paper by Chiari[2] on "The Structure of the So-called Fibromata of the Vocal Bands." The ground taken by the author of the paper was that these growths are inflammatory and not neoplastic, as they often show such inflammatory phenomena as œdema and hemorrhagic extravasations. This view seems to me to be thoroughly in accord with clinical observation.

Dr. Wright says that "it is a superficial, misleading, and dangerous proceeding to calmly describe growths as fibromata, myxomata, etc., when they are, in the vast majority of instances, nothing but different manifestations of chronic inflammation."

If such a pathology is correct, our views must be changed as to the relation of so-called neoplasms to all inflammatory processes, not only to that of a simple catarrh, but to the processes of syphilis and tuberculosis. In other words, what we have considered typical papilloma or fibromata of the larynx, accidents existing without apparent cause, may be rather manifestations of a simple catarrhal process, or a syphilitic condition, or perhaps the result of a tubercular germ.

This is most interesting pathologically, and important clinically, because it is quite possible that some of the cases which we have been in the habit of diagnosing as forms of benign or malignant neoplasms are rather the manifestation of syphilis, and so may be benefited by the iodides. We do not believe that it has been the habit of laryngologists to prescribe iodides in cases of laryngeal growths. They have only been regarded and treated surgically. This pathology of laryngeal neoplasms, if true, will aid very much in the diagnosis of many growths which have been very difficult to classify; growths not typical, and which always have seemed to bear an intimate relation to some constitutional disease. If these growths are inflammatory, we shall be encouraged to ascertain what kind of inflammatory process is behind them.

A benign growth may therefore be an earlier manifestation of tuberculosis than we have hitherto recognized. A causative relation of some of them to syphilis may be established, and the remedy will then be apparent.

All laryngologists admit the difficulty of always being able to diagnose growths in the larynx. Dr. Delavan,[3] in a carefully written article on the "Early Diagnosis of Malignant Disease of the Larynx," said: "We are taught that cancer, syphilis, tuberculosis, and lupus all present characteristics which distinguish them to the eye, but unfortunately this is not true." And further he said that "a large number of cases in which the microscope has revealed tubercular disease have proved to be malignant when more carefully examined microscopically later on." We know that malignant disease in its early stage may easily be mistaken for some phase of syphilis or tuberculosis.

Dr. Mulhall, of St. Louis, in the "Transactions of the American Laryngological Association" (1890, p. 96), said that he had had two cases of cancer of the larynx which had been greatly improved by the iodide of potassium.

The late Dr. Hooper,[1] of Boston, in examining 7,500 patients having laryngeal disease, found only 21 benign neoplasms. Papilloma occurs more frequently than all the other forms combined. A good diagnostic point about benign growths is that they are rarely subglottic.

Sarcoma exists still more infrequently. Butlin[2] found only 23 cases recorded. In 848 cases of sarcoma Gurlt[3] found only one of the larynx. Sarcoma seems to involve the lymphatics much less frequently than does the more common form of cancer—epithelioma. Gurlt,[4] in reviewing the literature, found that epithelioma involved the larynx but sixty-three times out of 11,131 cases of epithelioma occurring everywhere.

The terms carcinoma and epithelioma seem to be used synonymously. Of 24 cases of carcinoma, 23 were epithelioma and 1 was of medullary character.

I cannot enlarge here upon the diagnostic points of malignant disease. It is easy sometimes to mistake it for syphilis and tuberculosis. A discussion on the diagnosis of malignant disease brought out such salient diagnostic points, as greater general thickening and infiltration of the larynx than in other diseases, and an inflammatory areola surrounding the base of the growth; and with this infiltration there generally follows loss of motion of the side of the larynx involved, and this often without involvement of the crico-arytenoid articulation, the immobility being caused by infiltration of the muscular tissue.

Pain in the ear is considered a significant symptom. But, after all, the microscope must be the final court of appeal. But it is often necessary to wait for some months before a satisfactory portion of the growth can be obtained for microscopical examination. It would be unwise to dig into a deeply situated enlargement of the larynx beneath unbroken mucous membrane, just for the purpose of obtaining a microscopical specimen, so that it is wise to ascertain the effect of the iodide while we are waiting. There is difficulty, too, in securing enough of the growth to positively acquaint us with its histological character. Wright says that "small, round-celled sarcoma, granulation tissue (syphilitic or tubercular), and lymphoid hypertrophy, are frequently indistinguishable under the microscope." But even in cases which have every appearance of malignant disease, I believe the conservative physician will always give the patient the benefit of the iodide and mercury.

It is my belief that extirpations of half the larynx have been performed by surgeons at an early stage, in undoubted cases of syphilis, where anti-syphilitic treatment would probably have effected a cure.

Dunn, of Richmond,[5] reports a case of laryngeal growth, which had every appearance of malignancy, which disappeared after the application of compound tincture of iodine.

We might continue to cite cases of most varied pathological appearances—ulcerations which seemed to be tubercular, small growths which were apparently benign, large swellings with every appearance of malignancy—which were afterward proven to be specific, or which disappeared, at least, through the effect of iodide of potash. This drug and the microscope cannot be ignored in searching for a truthful diagnosis.

A FURTHER REPORT ON ACHYLIA GASTRICA.[1]

By MAX EINHORN, M.D.,

NEW YORK.

In 1892 I suggested the term "Achylia Gastrica"[2] for those conditions in which the stomach apparently secretes no juice and in which clinically the diagnosis of "atrophy of the gastric mucosa" seems to be justifiable. In my paper referring to this subject I endeavored to show that cases of achylia gastrica and cases of pernicious anæmia ought to be kept strictly apart. Whereas the latter, as a rule, ends fatally, the former does not necessarily endanger the life of the patient. As a proof of this view I described a case of achylia gastrica which I had under observation for four years and whose condition had, meanwhile, rather improved, and another case in which the obtained historical points made it probable that the stomach had persisted in this state of juicelessness for forty years. In this case there were no subjective symptoms present and the patient used to partake of the heaviest food with perfect impunity. In all these cases the small intestine acts vicariously and completely replaces the lack of digestion of the stomach.

In regard to the literature of "atrophy of the gastric mucosa" the same can be found in my above mentioned paper. I would like, however, again to pay my tribute to the excellent work done in this line by Henry and Osler[3] and F. P. Kinnicutt.[4] Both papers describe cases of pernicious anæmia in which the autopsy showed the disappearance of the gastric glands. Henry and Osler have given various characteristic drawings illustrating the microscopic picture of this condition.

The recent literature on cases of pure achylia gastrica (not complicated with pernicious anæmia) is not very extensive. Simultaneously with my article on "Achylia Gastrica" Ewald[5] published a paper entitled: "A Case of Chronic Disability of Gastric Secretion (Anadenia Ventriculi?)." Ewald's views are in perfect accordance with mine. The patient reported in the paper had been observed by Ewald for two and a half years. Whereas this patient improved considerably in every respect and gained forty-two pounds in weight, the chemical examination of the gastric contents showed a total lack of juice.

Th. Rosenheim[6] reports a patient, aged eighteen, who presented all the symptoms of achylia gastrica in 1889, and when examined anew in July, 1894, the same condition of the stomach was found.

Westphalen[7] described a case of achylia gastrica complicated with motor insufficiency. Here the diagnosis made during life was verified by autopsy after patient's death a few days after an operation.

In his text-book on "Diseases of the Stomach," J. Boas[8] says: "There is at present no doubt that an absolute and permanent lack of gastric secretion may be compatible with a subjectively and objectively perfect welfare. . . . Instead of many one striking instance. . . . The patient, under observation for over three years, partakes of the heaviest foodstuffs without any discomfort whatever, notwithstanding the absolute lack of HCl and almost entire absence of the enzyms."

In this country Allen A. Jones[9] has described under the name of "Gastric Anacidity" four cases belonging to this class of affections.

It would have been hardly necessary to again discuss this subject but for two new facts observed which appear to be of value for the affection in question.

As yet it is uncertain whether in all cases of achylia gastrica there necessarily exists an anatomical lesion (atrophy of the glands) or not—*i.e.*, whether cases of achylia might not perhaps occur, in which the gastric mucosa is not much altered. The question of the possible existence of achylia when there are no considerable changes of the gastric mucosa is closely connected with the further question, whether a repair of this condition be possible.

The two following observations will perhaps throw some light on these questions:

CASE I.—M. G——. *Diagnosis: Achylia gastrica, Erosiones ventriculi.*—The details of this case are given in my paper[1] on "Erosions of the Stomach." Here it will suffice to state that the chemical examination of the gastric contents of this patient—which analysis has been made far more frequently than described in my paper—always revealed a total absence of HCl, an acidity of four or even below that, absence of the biuret reaction, and absolute deficiency of the rennet and pepsin ferments. In this way the diagnosis of achylia gastrica had been established. In the same patient lavage, in the fasting condition, used to bring up several small pieces of gastric mucosa, which, microscopically, showed the presence of rather normal glands. (In my above-named paper on "Erosions of the Stomach" there is a drawing of the microscopic picture of a piece of gastric mucosa of the patient.)

It is evident from this observation that there might exist an achylia even when the glandular layer of the stomach has not been totally destroyed. The suppression of the gastric secretion is, then, probably caused by certain nervous disturbances.

CASE II.—Louis T——, now twenty-eight years of age, with previous diagnosis: Achylia gastrica (reported in 1888 in the *New York Medical Press*, and thereafter, in 1892, in the MEDICAL RECORD)—still presented the symptoms of achylia gastrica in 1893. In 1894, however, the patient began to show a different aspect of his gastric functions. At first it was noticeable that the gastric contents consisted of a much finer mixture—the solid particles being much more minute—contained the two characteristic ferments, presented a low degree of acidity (though higher than heretofore), and revealed the presence of peptone. A few months later the acidity increased to thirty, and now even free HCl could be easily detected.

In this case, in testing the gastric contents in 1893, I also applied Sjoequist's method as modified by Ewald[2] in order to determine whether there was combined HCl. The result was always negative. I have applied the same method (Sjoequist-Ewald) in three other cases of achylia gastrica, and could always determine a complete absence of combined HCl.

According to my belief, in cases in which the acidity has either disappeared or is so low that it does not exceed four or six for a long period of time, it is sufficient, for practical purposes, to ascertain the absence of the ferments (pepsin and rennet), of Günzburg's reaction and of the biuret test, in order to make the diagnosis of achylia gastrica. I am quite certain that one would find also in all these cases a total lack of the combined HCl, just in the same manner as I found it in the three cases I have especially examined with regard to this point.

If I now return to case Louis T——, it appears quite evident that even a typical case of achylia, where this

[2] Proceed as follows: To 10 c.c. of the filtrate add $BaCO_3$, evaporate to dryness, and reduce to ash. Dissolve the residue in H_2O. If, on addition of a solution of Na_2CO_3, no precipitate is formed, it shows that no barium chloride is present, or that there was no combined HCl present.

condition has remained unchanged for seven years (five years thereof under constant observation), may take a turn for the better and the stomach may slowly regain its secretory function. This fact appears to find only an explanation under the supposition that the suppression of gastric secretion in this case was not due to a total disappearance of the glandular layers, but rather to certain thus far unknown nervous disturbances.

Both cases mentioned prove that achylia gastrica may exist in a person notwithstanding the presence of gastric glands.

From the above it is apparent that the clinical picture of achylia gastrica does not suffice to establish the diagnosis of anadenia ventriculi (Ewald). It does not, however, by any means follow that some cases of achylia gastrica might not be complicated or rather caused by anadenia.

The following case that was observed for several years, and on which ultimately an autopsy was made, will be of great interest with regard to the point in question :

Mrs. Augusta G——, about thirty-eight years of age, came under my care through the kindness of Dr. J. Rudisch in 1888. The patient stated she had suffered severely from the stomach for the last five years. She frequently had pains after meals. There was no vomiting. Constipation. During these five years patient had lost considerably in weight—about twenty pounds altogether.

The examination of the chest organs did not show anything abnormal. Palpation of the abdomen did not reveal any tumor. There was no splashing sound in the gastric region and the contours of the stomach could not be mapped out. By abundant food and massage the condition of the patient greatly improved. She increased seven pounds in weight during the winter, and the pains were slight or absent. During the summer of 1888 I examined the gastric contents one hour after Ewald's test-breakfast. The contents obtained were small in quantity and thick. The bread particles were not minute and looked unchanged. The amount of fluid was extremely small. The filtrate showed : HCl = 0 ; acidity = 4 ; rennet = 0 ; biuret reaction = 0 ; erythrodextrin = 0 ; sugar +.

In the fall of 1888 I again examined the gastric contents and obtained exactly the same result. Patient in the summer of 1889, although feeling quite well, left for Europe. She stayed a few weeks in Franzensbad, and then about two months in a hydropathic institute near Vienna. When patient returned to New York she was not not, on the whole, better than heretofore. During the winter of 1889–90 she had a severe attack of pleurisy, from which she recovered perfectly. Patient spent the summer of 1890 in the Catskill Mountains. While there she caught cold and suffered from a new attack of pleurisy with considerable exudation. After aspirating over a quart of liquid with the Dieulafois apparatus patient seemed to recover quickly. Soon afterward, however, a new serious ailment—carcinoma uteri—made its appearance and ended her life on September 11, 1891.

During the last eighteen months of patient's life the gastric symptoms were not very pronounced. Patient used to eat very slowly, and always made intermissions (for about two to three minutes) after every few mouthfuls of food. She asserted that without the intermissions the food would not go down and remained in the œsophagus. Patient, however, partook of a quite manifold and varied diet (meat, green peas, spinach, asparagus, different soups, white bread and butter, milk, coffee). In order to alleviate the pains caused by the cancer—pronounced inoperable by the best gynecologists of this city—methyl-blue 0.2 once a day was administered first per os, then per rectum. This medicament was used in this case a whole year with the greatest benefit. During the entire sickness the nutrition of the patient remained quite good. About three months before death a resistancy was felt below the ensiform process which was ascribed to the stomach. It was quite natural to think of a cancerous growth in this organ also. This, however, was not the case, as the autopsy afterward showed.

At the autopsy the uterus was found to be of the size of a child's head, and taken up by a scirrhous cancer. At the beginning of the colon ascendens there was a perforation (caused by the pressure of the tumor on that organ) ; pus in the abdominal cavity.

For a better conception I give the following drawings :

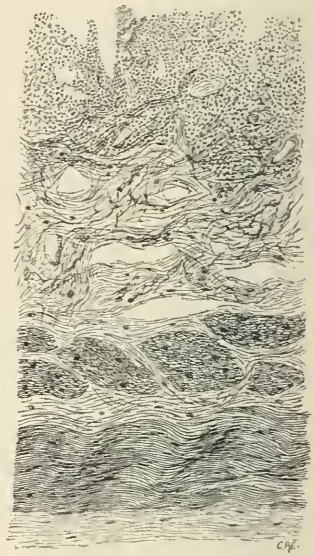

Fig. 1.—Cross-section through the Stomach-wall under Low Power, showing Relations of the Layers : *a*, mucosa ; *b*, submucosa ; *c*, *d*, muscularis ; *e*, peritoneum. No glands in the mucosa.

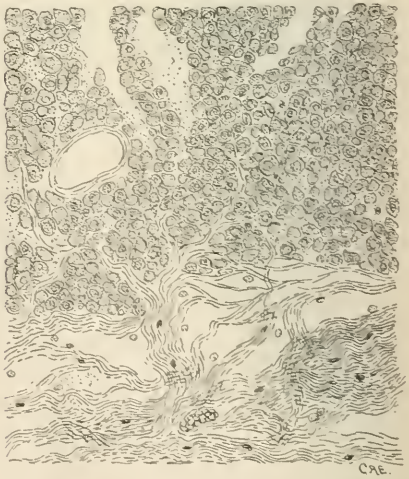

Fig. 2.—One part of the two inner layers highly magnified : *a*, mucosa ; *b*, submucosa.

The stomach was not adherent to the neighboring organs ; it looked extraordinarily small and firm, of large

pear's size, and measured 10 ctm. in length and 6 ctm. in width, the walls being about 1 ctm. thick. In opening the stomach the interior appeared quite smooth, presenting a whitish gray surface. The pylorus was not stenosed, and could be passed with the finger.

From two different spots of the fundus ventriculi numerous microscopical specimens were made, showing the entire cross-cut of the wall of the stomach. No glands could be found anywhere, and instead of them there was a thin layer consisting principally of round cells. The submucosa was greatly hypertrophied and filled with numerous cyst-like meshes. The muscularis was also very much thickened.

Conclusions.—In this case the diagnosis of achylia gastrica had been made three to four years before death. An abundant and well-regulated dietary regimen had considerably improved the patient's condition. The state of the stomach was bearable and remained so. A cancer of the uterus, however, developed and ended the life of the patient. At the autopsy the stomach was found to be very small in size and its walls uniformly thickened. The inner surface presented a smooth and whitish appearance; microscopically the inner layer was found to contain no glands, and consisted merely of cells and scanty fibrous tissue. The other layers of the stomach, the submucosa and muscularis, were greatly hypertrophied, not containing, however, any foreign elements. Thus, the condition of the stomach found at the autopsy corresponded to that of cirrhosis ventriculi, as described by Nothnagel,[1] Henry and Osler,[2] and von Kahlden.[3]

In this case it seems justifiable to assume that the achylia gastrica, which was diagnosticated about three years before the exitus, was due to a real anadenia of the organ. It appears, however, more than probable that the great diminution in the size of the stomach developed in the last three or five months before death, at the time when the resistancy began to be felt at the ensiform process.

Out of the entire number of my newly observed cases of achylia gastrica (they amounted to thirteen after deducting the above-narrated cases), I may be allowed to report two typical cases of this affection, one of which was interesting, inasmuch as there were no gastric symptoms whatever and the complaints appertained merely to the intestinal tract.

Typical Cases of Achylia Gastrica.—The following cases are of great interest:

Case I. (October 24, 1892).—Mrs. G——, aged about forty-five, complains of her stomach for the last twelve years. She is almost always troubled with pains after meals in her gastric and epigastric region. Appetite poor. Bowels inclined to be constipated. Vomiting appeared very seldom. Patient had lost considerably in weight during the first years of her ailment; thereafter her weight remained stationary. In 1891 she visited Carlsbad, but her condition did not improve any.

Present Condition.—Patient of small stature and quite thin. Panniculus adiposus looks somewhat thin. Lips and cheeks of a pale color. Tongue not coated. Chest organs in good shape. The palpation of the abdomen reveals the absence of any tumor. The epigastric region is sensitive to pressure, but not exactly painful. A splashing sound can be produced to about three fingers' width below the navel. The urine does not contain either sugar or albumin.

October 27th.—Examination of the stomach one hour after Ewald's test-breakfast: HCl = 0; lactic acid = 0; acidity = 6; rennet = 0; biuret reaction = 0; erythrodextrin = 0; sugar +. The quantity of the gastric contents is not large, and contains a very small amount of liquid. The bread particles are not minute. No mucus.

October 30th.—When fasting: stomach empty.

January 8, 1893.—Examination of the stomach one hour after Ewald's test-breakfast: HCl = 0; lactic acid = 0; acidity = 4; rennet = 0; pepsin = 0; biuret reaction = 0; erythrodextrin = 0: sugar +.

During the year 1893 several other examinations of the gastric contents had been made, with the same analytical data as just mentioned.

Taking into consideration the very long period of the ailment and the result of the chemical examination of the gastric contents, achylia gastrica was diagnosticated, and cancer excluded. The further course of the patient's condition has fully verified this assumption, for the patient now (two to three years after the reported examinations) is in rather a better condition than heretofore.

The treatment consisted in occasional lavage and intragastric faradization.

Case II. (October 1, 1894)—Mrs. A. S——, aged about twenty-five, had suffered five years ago from severe diarrhœa for about three months. Eighteen months later patient had a new attack of diarrhœa lasting over a month. About a year ago she began to complain of pains after meals. These pains, as a rule, appeared right after the partaking of food and lasted for about three hours. At times, patient would experience a mere feeling of pressure, at times, however, the pain was very intense in character. Bowels regular. For the last two years she suffered from very severe headaches. Patient had lost seven pounds during the last year. She greatly suffers from belching without any bad odor. Appetite very good. Patient, at times, feels very sleepy, at times again she is subject to fainting spells of very short duration.

Present Condition.—Patient looks well nourished, though somewhat pale. Tongue slightly coated. Chest organs intact. The stomach is situated quite low (gastroptosis) and the right kidney movable. The epigastric region is sensitive to pressure, although not painful. The urine does not contain anything abnormal.

October 2, 1894.—Examination of the stomach one hour after Ewald's test-breakfast. Only a small quantity of thick contents could be obtained. The bread particles are not minute and they obstruct the tube.

The filtrate shows: HCl = 0; reaction hardly acid; acidity = 2; lactic acid = 0; biuret reaction = 0; rennet = 0; pepsine = 0; erythrodextrin = 0; sugar +.

October 4th.—In the fasting condition: stomach empty. Patient is treated every other day with intragastric faradization. She feels better and can eat without pains; the headaches have meanwhile disappeared.

October 17th.—Examination of the stomach one hour after Ewald's test-breakfast: HCl = 0, of hardly acid reaction; acidity = 2; lactic acid not present; biuret reaction = 0; rennet = 0; pepsin = 0; erythrodextrin = 0; sugar +. The bread particles not minute; small quantity of fluid; no mucus.

At the end of November, 1894, patient was dismissed from treatment. During the last two months she had gained eight pounds in weight and was believed to be perfectly well. The examination of the gastric contents of November 29, 1894, however, revealed exactly the same condition as previously described.

April 5, 1895.—Patient felt well all the time without any treatment. The gastric contents were again examined and found to contain the same characteristic properties as above stated.

A Case of Achylia Gastrica with Predominant Intestinal Symptoms (April 14, 1894).—Solomon S——, fifty-seven and a half years of age, always enjoyed good health until August, 1892, when he had a severe attack of dysentery (patient had to stay in bed for over three weeks and felt afterward extraordinarily weak). Since that time patient had attacks of severe diarrhœa (much mucus, sometimes blood in the passages) every two to three weeks. This diarrhœa used to alternate with

[1] Nothnagel: Deutsch. Arch. für klin. Med., 1879, Bd. 24, p. 353.
[2] Henry and Osler: Loc. cit.
[3] Von Kahlden: Centralbl. f. klin. Med., 1887, No. 16, p. 281.

constipation. From August to October, 1892, patient had lost forty pounds in weight. From that time on he felt weak and miserable and complained of thirst. This condition remained unchanged during this time. He complains at present principally of extreme weakness, of intense thirst, and of very weakening diarrhœal attacks.

Present Condition.—Color of lips and cheeks very pale, anæmic. Tongue furred with a whitish coat. Chest organs intact. The stomach extends to one finger's width below the navel. A splashing sound can be easily produced in the gastric region. There is nowhere any tumor. There are no sensitive spots discoverable in the abdomen. The knee reflex is present. The urine contains neither sugar nor albumin.

Patient was treated for some time, at first, with injections into the bowels (acid. tannic. 2.0 to a quart of water once daily), thereafter with the administration of peptonate of iron. All these means, however, failed to be of any benefit whatever; the tired feeling and weakness persisted, and the frequent attacks of diarrhœa likewise remained unchanged.

November 21, 1894.—Examination of the stomach one hour after Ewald's test-breakfast: HCl = 0; acidity = 2; lactic acid = 0; rennet = 0; pepsin = 0; biuret reaction = 0; erythrodextrin = 0; sugar +. Quantity of liquid very small; the bread particles not minute; no admixture of mucus.

November 23d.—When fasting: stomach empty. Achylia gastrica is diagnosticated, and the patient treated with intragastric faradization. The diet is arranged in such a manner that it does not contain very much meat, and is, instead, rich in food taken from the vegetable kingdom.

After two weeks of this treatment the sensation of weakness remained away. Patient began to look better. His cheeks had a red color, the bowels were regular, and the troublesome sensation of thirst that formerly was so annoying to the patient disappeared.

December 17th.—Examination of the stomach one hour after Ewald's test-breakfast: HCl = 0, of neutral reaction; biuret reaction = 0; rennet = 0; pepsin = 0; erythrodextrin = 0; sugar +. Small quantity of fluid; the bread particles not minute; no mucus.

Patient asserts that he feels well; he can walk great distances without feeling tired.

December 20th.—One and a half hour after the test-breakfast: stomach empty.

December 31st.—Patient takes one glassful of milk; one hour afterward, he takes a glassful of water, and his stomach is directly faradized for ten minutes. Then the gastric contents are obtained by means of a tube; they consist of uncurdled milk diluted with water and are of neutral reaction.

Patient was examined at various times in January and February, 1895, and there was always found a complete absence of gastric juice. The absorption of the stomach was examined by means of the KJ test, and the iodine could be detected in the saliva after a lapse of eleven minutes. Patient's health was and remained thus far in very good state; his appetite is fair, bowels regular, and stools well formed; no attacks of diarrhœa.

April 15, 1895.—Patient has gained ten pounds in weight.

(Several examinations that have been made with regard to the acidity of the urine are here omitted, as they will be mentioned later.)

Of the remaining patients with achylia gastrica I may be permitted to give in table form a short review of the subjective complaints and of the objective data found.

TABLE OF THE REMAINING CASES OF ACHYLIA GASTRICA.

Number.	Name.	Years of Age.	Duration of Disease (Years).	Principal Complaints.	Position of the Stomach.	Result of the Chemical Examination One Hour after Ewald's Test-breakfast.	Remarks.
1	Patrick M.....	46	30	Dizziness, principally after meals.	Stomach very large; extends to one hand's width below navel.	The particles of roll not minute. HCl = 0, acidity = 4, rennet = 0, biuret = 0, erythrodextrin = 0, sugar +.	Stomach, when fasting, always empty.
2	George H. J....	63	1½	Pains, beginning at meals and lasting for about two hours.	Extends to about one finger's width above navel.	The pieces of bread not small. HCl = 0, lactic acid = 0, acidity = 4, rennet = 0, biuret = 0; no mucus; small quantity of fluid.	Stomach, when fasting, empty. Patient has not lost any in weight, and looks well nourished.
3	Mrs. H. B.....	42	2	Pains after meals; belching; at times regurgitation of food.	Gastroptosis.	Three-quarters of an hour after test-breakfast: The bread particles not minute. HCl = 0, acidity = 2, rennet = 0, pepsin = 0, biuret = 0; no mucus.	One hour after the test-breakfast the stomach had been frequently found empty. Patient had gained eight pounds during three months of treatment. The condition of the stomach, however, has not changed in any way. Right kidney movable.
4	Mrs. P. A. ...	40	7	Pains after meals; frequent vomiting; constipation.	Stomach sunken down but not enlarged.	The particles of bread unchanged. HCl = 0, hardly acid; acidity = 2, rennet = 0, biuret = 0, erythrodextrin = 0, sugar +.	Stomach empty in the fasting condition.
5	Mrs. Johanna S.	50	3	Pains after meals; at times vomiting; frequent diarrhœa.	In normal position and not enlarged	The particles of food not small; small quantity of fluid. HCl = 0, acidity = 2, rennet = 0, pepsin = 0, biuret = 0; no mucus.	Stomach empty, when fasting. After a few times of lavage the pains subsided, the vomiting and diarrhœa disappeared; notwithstanding this, the chemical condition of the gastric contents did not change in any way.
6	David S...	36	15	Frequent attacks of diarrhœa and dizziness.	Extends to the navel.	The pieces of roll not minute and unchanged. HCl = 0, lactic acid = 0, acidity = 4, rennet = 0, pepsin = 0, biuret = 0, erythrodextrin = 0, sugar +.	Stomach empty when fasting. Patient looks perfectly well and robust, has a good appetite (slightly increased), and partakes of the heaviest food with impunity.
7	Mrs. C. W....	46	4	Pains after meals; poor appetite; frequent diarrhœa.	Gastroptosis.	The particles of bread unchanged. HCl = 0, lactic acid = 0, acidity = 4, rennet = 0, pepsin = 0, biuret = 0, erythrodextrin = 0 sugar +.	Right kidney movable. Stomach empty when fasting. One hour after the test-breakfast the stomach was found empty several times. Patient was under observation for a whole year and had gained seven pounds; she then died, after a short illness, with pneumonia.
8	Isaac S.... ...	46	15	Pains after meals; sometimes headache; frequent diarrhœa.	Extends to the navel.	Three-quarters of an hour after test-breakfast: The pieces of bread not minute. HCl = 0, lactic acid = 0, acidity = 4, rennet = 0, pepsin = 0, biuret = 0, erythrodextrin = 0, sugar +.	One hour after the test-breakfast the stomach, as a rule, used to be found empty. The absorption of the stomach was examined by means of KJ: in twelve minutes iodine could be detected in the saliva. Patient was under observation for over a year. There was a decided improvement in the patient's condition. He has gained six pounds in weight; there were hardly any pains, and the diarrhœa appeared only very seldom. The chemical examination of the stomach, however, showed the same condition as described.
9	Mrs. B. M....	32	5	Pains after meals; frequent belching; sometimes vomiting, obstinate diarrhœa.	Gastroptosis.	The pieces of bread not small. HCl = 0, acidity = 0, rennet = 0, pepsin = 0, biuret = 0, erythrodextrin = 0, sugar +.	Right kidney movable. Here Sjoecquist's method, as modified by Ewald, was applied in order to determine the quantity of combined HCl; no traces, however, could be detected. The treatment consisted principally in intragastric faradization. There was marked improvement. Patient gained six pounds in weight; the pains and the diarrhœa entirely disappeared.
10	Augustus A	47	6	No gastric symptoms; obstinate diarrhœa, alternating with constipation.	Stomach enlarged.	The particles of bread not minute. HCl = 0, acidity = 4, rennet = 0, biuret = 0, erythrodextrin = 0, sugar +.	Right kidney movable. Pronounced nervous symptoms. Tongue always clean. Patient was under observation for four years. His condition has not changed in any way during this period of time. His weight remained the same, and his subjective and objective symptoms persisted in an unchanged manner.

Symptomatology. — Whereas the subjective complaints, as is easily apparent from the above-mentioned cases, may be of quite a manifold nature and may often be entirely absent, particularly as regards the stomach, the objective symptoms are always present. In reference to this point I expressed myself in my paper on "Achylia Gastrica" in the following way:

"In all four cases the stomach contents showed, one to one and a half hours after Ewald's test-breakfast, the following peculiarities: 1. The pieces of roll are not minutely minced and unchanged. 2. The reaction very weakly acid or neutral, usually the acidity was 4 (*i.e.*, 100 c.c. of the filtrate of the stomach contents are saturated by 4 c.c. of a one-tenth standard solution of sodium hydrate). 3. Hydrochloric acid not present. 4. Lactic acid present, but could be discovered only after a thorough shaking with ether. 5. Neither propeptone nor peptone present. 6. The tests for the pepsin and rennet[1] ferments gave negative results. 7. The stomach contents did not smell badly, and did not otherwise give the appearance of decomposition."

To these seven points I would now add as point 8, absence of mucus, and 9, the remarkably small quantity of liquid found in the stomach of these patients one hour after the test-breakfast. Aside from the fluids soaked in and around the particles of bread there is hardly any liquid at all. The gastric contents thereby acquire a peculiar, characteristic appearance, and look different from what they do in other affections of the stomach. This small amount of fluid in the gastric contents of patients with achylia may be explained in the following way: Besides the water (or tea) ingested into the stomach with the test-meal, there is no addition of juice (or liquid) during the stay of the food in this organ. As the more liquid chyme, as a rule, leaves the stomach quicker than the more solid substances these latter alone will then, after awhile (about one hour after Ewald's test-breakfast), be found present.

The motor function of the stomach was not impaired or slackened in any of my patients; in some of them rather somewhat hastened (I. S—— and Solomon S——).

The absorption faculty of the stomach I have examined in three of these patients and did not find it in any way retarded. (In patient L. T—— after 0.2 KJ the reaction for iodine appeared in the saliva after eight minutes, in I. S—— after twelve, and in Solomon S—— after eleven minutes.)

In what condition is the acidity of the urine in patients with achylia gastrica?

It appeared to me of interest to pay attention to this point, and more especially to ascertain whether there is any difference in the degree of acidity of the urine passed in the fasting condition and that emptied during the act of digestion. As is well known, normally there is a decrease of the degree of acidity of the urine during gastric digestion. This is explained by the fact that at that time the acid elements are conducted, so to say, to the stomach. This point, however, does not apply to achylia gastrica, for there is no acid secretion in the stomach. For this reason it would theoretically appear correct to assume that in achylia gastrica the acidity of the urine in the fasting condition and during digestion would not vary very much. The following experiments go to show that this is really the case.

The experiments were conducted in the following manner: The patient arising early in the morning empties his bladder; half an hour later he urinates and puts it in a bottle with the mark "U. I." (urine first=fasting). He then takes Ewald's test-breakfast. One hour afterward he again urinates and marks the bottle with "U. II." (urine second = during digestion). His gastric contents are then obtained. All the samples are thereupon examined. In this way the relation between the acidity of both urines and the gastric contents can best be studied.

Case I.—L. T——, September 28, 1888. One and a quarter hours after Ewald's test-breakfast: HCl = 0; neutral reaction; rennet = 0; biuret reaction = 0; erythrodextrin = 0, sugar +.

U. I., acidity = 28. U. II., acidity = 30.

Case II.—S. S——, February 16, 1895. One hour after the test-breakfast: HCl = 0; reaction hardly acid; acidity = 4; biuret reaction = 0; rennet = 0; rennet zymogen, hardly traces. Bread particles not minute; small amount of fluid.

U. I. (specific gravity = 1.030), acidity = 44.

U. II. (specific gravity = 1.020), acidity = 44.

Experiment III.—Same patient, April 12, 1895.

U. I. (specific gravity = 1,020), acidity = 52.

U. II. (specific gravity = 1,022), acidity = 54.

Thus, in these two cases of achylia gastrica the acidity of the urine before and during gastric digestion hardly varied at all.

Etiology.—With regard to the etiology of achylia gastrica it is generally assumed that same develops after preceding grave chronic catarrhal conditions of the stomach. The newer text-books on "Diseases of the Stomach" (Ewald, Boas, Bouveret) mention this affection in the chapter on "Gastritis Glandularis Chronica." I certainly believe that such an origin of achylia gastrica is sometimes the case. The cases of chronic gastric catarrh in which the acidity is pretty low (10 to 20), no free HCl exists, but biuret reaction and likewise rennet are present, speak in favor of this view. They represent, so to say, the preceding stage of achylia gastrica. Notwithstanding this, it seems to me more than probable that the affection in question may establish itself also in some other way (in consequence of nervous disturbances). In such instances the glandular layers of the stomach need not, necessarily, be greatly altered, although it appears probable that after a long persistence of inactivity of the glands these may begin to atrophy. The above-mentioned cases, M. G—— and L. T——, prove the possibility of a nervous origin of achylia gastrica.

Prognosis.—The prognosis of cases of achylia gastrica is good *quoad vitam*, which view I have represented in my previous papers and is now generally accepted by most writers. The small intestine perfectly replaces the digestive work of the stomach, and the organism is not only enabled to maintain its equilibrium but also to gain in weight. The above case of Ewald shows that very clearly (patient had gained forty-two pounds); some of my own cases likewise prove this fact.

Treatment.—With regard to the therapy, such will be necessary only in those cases in which there are some subjective complaints.

The treatment will have to be carried out in the two following directions: 1. To stimulate the mechanical action of the stomach. 2. To arrange the diet in such a way that same is easily accessible for the intestinal digestion.

The first point is best achieved by stimulating the stomach, as by lavage and, principally, direct faradization of the organ. In some of the cases I have not applied any medicaments whatever, in some I have administered condurango or nux vomica.

In reference to diet it is of utmost importance to see that the food is broken into very minute particles or can be easily done so by chewing. For, on the one hand, all kinds of meat are not altered in any way in the stomach and reach the intestine in the same shape as when they entered the cardiac orifice; on the other hand, the starchy substances contained in the vegetable food cannot become converted into maltose as long as the albuminous membrane occluding them has not been opened.

In the stomach of these patients starch, as such, when accessible to the action of ptyalin, undergoes conversion into sugar very rapidly.

[1] The rennet zymogen, however, may still be found present.

The vegetable food is, as a rule, here very well borne. Strained pea- and bean-soups may be recommended very highly on account of their richness in albumen. Kumyss or matzoon, or sometimes bonny-clabber well beaten with a spoon, or plain milk with the addition of bread or crackers with butter are highly commendable. Permit meats only in small quantities, best well hashed and broiled or the white part of chicken. Brain, sweetbread, fish, and raw oysters are very suitable. In the grave cases it is advantageous to administer meat powder (two to three tablespoonfuls or even more, pro die, in soup or milk). The usual beverages, as tea, coffee, cocoa with milk and sugar, besides small quantities of beer or stout, are allowed.

Here also, like in all other chronic disturbances of the digestive tract, it will be of importance to pay attention not only to the quality but also to the quantity of food taken. And here the greatest stress must be laid that a sufficient quantity of food is taken. It is always preferable to have patient partake of a too big quantity of food rather than of a too small one, by which a condition of subnutrition is so often established.

When the intestine has adapted itself to the greater amount of work and the nutrition goes on a well-regulated basis, the achylia gastrica need not cause any trouble whatever, and the patient may enjoy perfect euphoria.

20 East Sixty-third Street.

A CASE OF ICHTHYOSIS CONGENITA WITH SOME UNUSUAL FEATURES.[1]

By JOHN CABOT, M.D.,

CLINICAL ASSISTANT, VANDERBILT CLINIC, DERMATOLOGICAL DEPARTMENT, NEW YORK.

My aim being to present a practical contribution, I shall omit all general references and discussion, and confine myself to reporting the case, with a brief *résumé* in conclusion.

Bertha Z——, fourteen months old, born in this country of German parentage, sent to me through the kindness of Dr. Philip Roth, Jr., of Newark, N. J., and first seen November 10, 1894.

The history, as gathered from the mother, is that both parents and two older children, of ten and seven years of age respectively, are healthy. The mother has had no miscarriages or premature births before, but says that this child was born at seven months of utero-gestation, although her abdomen was more distended than with either of her other children at full time. She was four days in labor, with gushes of a watery fluid, accompanied by uterine pain, every half-hour or so, with constant dribbling between pains. The child was weak and marasmic when born. The mucous membrane of the eyelids was much inflamed, ectropion existing. The eyes were open, and there was inability to close them. The nostrils were occluded, and there was difficulty in breathing, so that for some days it was expected to die at any moment.

The skin was thickened, dry, red, and scaly over the entire body at birth, with scales from pin-head size to one and a half inch square, the largest being on the trunk.

Dr. Roth writes, in answer to my inquiry: "In regard to Bertha Z——'s case, would say that there was a great deal of hydramnios, so much so that when I ruptured the bag it seemed to me that it might have been about two gallons. The child was in normal position, L.O.A., and delivered easily. I will state here that I delivered the woman three times, the other children being perfectly healthy. When Bertha was born she presented the appearance of a Chinese baby, the outer canthi of the eyelids were drawn downward and inward, almost completely closing eyeballs from view. There was no vernix caseosa on child's head or body, it being perfectly dry when born. The nose was like a white, bony prominence protruding from the face, giving it a most ghastly look; the angles of the mouth were tightly drawn downward and inward, and had a cracked appearance. The ears were bound down to the head and were immovable, and looked as though they were gangrenous. There was no hair on the child's head; both nares were closed, so that I had to make an incision into each one to allow the child to breathe; the rest of the body, that is the skin, had the appearance as though the child was enveloped in oil-silk, shrivelled, and not glistening, but dull."

The baby was nursed at the breast for a short time, but there was so much difficulty from the inability of the child to suck that it was spoon-fed with condensed milk and water.

The marasmus continued for two months, after which time the child gradually gained in weight, and became healthy except for the skin lesion, and occasional attacks of bronchitis. At five months of age it had pertussis, followed by diarrhœa during the hot weather, when it again became marasmic, reviving slowly after a number of weeks' illness, and for the last two months has gained decidedly.

The eyelids were at first held firmly open, with about three-quarters of an inch interval between the upper and lower lids, the conjunctivæ being forced outward, thus diminishing the space of uncovered eyeball to about one-half an inch; this condition gradually improved under simple treatment to the point that the child is now able to bring the lids within half an inch of each other when asleep, the mucous membrane approaching to within one-eighth inch.

The hair was absent at birth, but has grown sparsely, and fallen out twice. The finger-nails have never been entirely normal, growing very long, rupial in character of late, beginning to drop from the fingers about three months ago until there is only one left.

The entire skin has been shed in different portions of the body from three to five times, that on the face and upper part of the body being most frequently thrown off, that of the lower limbs and scalp the least so; the skin peeling off in large and small flakes, leaving a reddened surface almost like natural skin, but which after a few days again becomes dry and wrinkled. In peeling off, islands of the old skin, tense and smooth, were often left, which when extending around the limb, formed tight bands and gave the appearance as if the child was outgrowing its own skin.

There has always been more or less heat in the skin; no moisture or perspiration was ever noticed.

The child has had much and varied treatment by many doctors, but without any effect.

Status Presens.—The child is well nourished, though somewhat smaller than it should be at fourteen months. Weight, 13 lbs. Length of body, 24 inches. Circumference of head, 17½ inches. Chest, 18 inches. Anterior fontanelle still open one-half inch. It is active and intelligent, but makes no effort to crawl or walk; is good-natured, and only restless when the clothing is too warm; takes cold easily. Heart, lungs, liver, and spleen negative; bowels regular. Pulse, 106. Respiration, 38. Urine clear, acid, 1.022; no albumin or sugar. No hair on the head. There is only one finger-nail, that on third finger of right hand; toe-nails normal. Ears thickened and lumpy in places; hearing normal. Eyes staring, from inability to close the thickened and stiff lids; ectropion. Sight good. The mouth is held half open, and the tongue is slightly enlarged; there are only two teeth, the lower incisors.

The hands and feet are stiffened, with almost no power of flexion or extension; the child being unable to grasp even large objects with the fingers.

The surface of the body feels warm to the touch, the thermometer showing 101.2° F. in axilla; 100.4° F. in rectum.

[1] Read before the New York Society of Dermatology and Genito-Urinary Surgery, March 20, 1895.

The skin over the entire body is slightly reddened, dry, hard, and scaly ; scales light gray in color, of papery consistency and from one thirty-second inch to 1 × 2 inches ; outlines polygonal, formed by the natural furrows in the skin. The skin is tense in places, notably on the left forearm, right leg, and left thigh and leg, where deep creases are formed by bands of the older skin extending round the limb, above and below which the flesh has seemingly filled out by recent growth, being raised one-quarter inch or more above the constricting bands, giving it a "hide-bound" appearance, which can be seen on the left leg in the photograph. This was taken soon after I first saw the child, and being necessarily an instantaneous exposure, is not as good as could be desired, but it serves to give an idea of the general appearance.

Surrounding the mouth, for an inch or more, the skin is almost natural, thin and white. On the upper part of the forehead is a line of demarcation where the old and new skin are in contact, that on the face being the fourth reproduction, that on the scalp the second or third.

November 28th.—On admission temperature 102° F. (Other physical conditions as noted above.)

November 29th.—Temperature, A.M., 100.8° F.; noon, 99.6° F. ; P.M., 102° F. Constipated. Olive-oil inunctions. Cascara, 3 ss.

November 30th.—Temperature, A.M., 99.8° F.; noon, 100° F.; P.M., 99° F. Stool, yellow and lumpy.

December 1st.—Temperature, A.M., 100° F.; noon, 101° F. ; P.M., 103° F. Ice cap. Cloths wet with equal parts linseed and cotton-seed oils to body. Wash of ichthyol and alcohol, āā 3 ij., aqua, ℥ j., to head, neck, and face. Liquid peptonoids.

December 2d.—Temperature, A.M., 100° F.; noon, 102.4° F.; P.M., 101° F.

December 3d.—Temperature, A.M., 102.4° F.; noon, 102.8° F.; P.M., 101.5° F. Ichthyol wash discontinued. Restless. Phenacetine, gr. j., at 10 P.M.

December 4th.—Temperature, A.M., 103.4° F. Ice cap. Noon, 101° F.; P.M., 103° F. Phenacetine, gr. j., at 9 and 1 P.M.

December 5th.—Temperature, A.M., 104° F. Ice cap. Noon, 101° F.; P.M., 100.8° F.

Treatment.—The child was put upon raw linseed oil, one drachm t.i.d., and enveloped in cloths wet with same material. Boric acid solution to eyelids.

November 16, 1894.—Skin about the same condition. Temperature, rectum, 100.2° F. ; axilla, 101.2° F. ; with surface thermometer on chest, 100.6° F. Pulse, 98. Respiration, 38.

November 23d.—Skin decidedly softer, eyelids come close together. Temperature, rectum, 99.8° F. ; axilla, 100.2° F. ; on chest, 100° F. Pulse, 96. Respiration, 36.

November 28th.—No change in skin. Temperature, rectum, 101.8° F. ; axilla, 102.6° F. ; on chest, 102.4° F. Pulse, 110. Respiration, 44. Cough, with fever and restlessness, since last visit. Physical examination shows no dulness on percussion ; auscultation is impossible, the crackling of the skin under the ear covering all other sounds. The mother says it always takes more or less cold in journeying back and forth from Newark to New York. On this account, and because it was thought that better facilities for constant observation and more regular applications could be had in a hospital than the mother could give at home, with her hands full of family matters, she was induced to leave the child at the Babies' Hospital, where it came under the care of Drs. L. Emmett Holt and E. B. Bronson.

Dr. Holt has obligingly placed the hospital records at my disposal, and from them I make extracts on the course of the disease as follows :

December 6th.—Temperature A.M., 100.2° F.; noon, 101° F.; P.M., 100.8° F. Considerable discharge from eyes. Boric acid eye-wash. Lanoline and vaselene, equal parts, to head. Cotton and linseed oils continued on body.

December 9th.—Temperature, A.M., 101.8° F.; noon, 102° F.; P.M., 104° F. Ice cap. Phenacetine, gr. j., at 9 and 11 P.M. Completely peptonized milk. Liquid peptonoids.

December 10th.—Temperature, A.M., 99.6° F.; noon, 102.4° F.; P.M., 100.4° F. Very restless in evening. 8 P.M., temperature, 104° F. Ice cap. Took very little of 7 A.M. bottle.

December 11th.—Temperature, A.M., 100.3° F.; noon, 102.4° F. Restlessness increasing, with short, sharp cry with every breath. Temperature, 10 P.M., 107° F. Ice pack for ten minutes gave great relief, and half an hour later temperature 100.2° F. Patient slept quietly. Stool yellow and smooth.

December 12th.—Temperature, A.M., 100.8° F.; 9 A.M., 108° F. Restless, with short, sharp cry. Four or five small round spots filled with serum over chest. Ice pack. Temperature falling to 100° F. Temperature at 4.45 P.M., 107.6° F. Ice pack, after which temperature did not reach 103° F., and patient slept quietly through the night. Whiskey, 3 j., in twenty-four hours.

December 13th.—Temperature, A.M., 100.6° F.; noon, 103.5° F.; P.M., 101° F. Seen by Dr. G. H. Fox, who pronounced it keratosis.

December 14th.—Temperature, A.M., 100.4° F.; noon, 102.5° F.; P.M., 98.4° F. Vomited at 5 P.M.

December 15th.—Temperature, A.M., 100° F.; noon, 104.2° F.; P.M., 101.4° F. Vomited 7 A.M.

December 16th.—Temperature, A.M., 101.4° F.; noon, 104.2° F.; P.M., 101° F.

December 17th.—Temperature, A.M., 103° F.; noon, 102° F.; 7 P.M., 107° F. Ice pack for eight minutes. Temperature, 8 P.M., 98.6° F. Peroxide of hydrogen to suppurating places on head.

December 18th.—Temperature, 3 A.M., 105° F. Ice pack. Temperature, 3.30 A.M., 98.6° F. At 3 P.M. vomited. Temperature, 100.2° F.

December 19th.—Temperature, 98.6° F.; 11 A.M., vomited. Noon temperature, 101.8° F.; 9 P.M., 105° F. Ice pack. 11 P.M., temperature, 97° F. Hot-water bags. Whole back of head is boggy and œdematous; stools gray.

December 20th.—Temperature, A.M., 100.2° F. Vomited at 8 A.M. Taken home by mother against advice. Skin slightly softer than on entrance.

December 22d.—Died with continuance of fever.

In reply to my inquiry as to what was, in his opinion, the direct cause of death, Dr. Holt writes: "The thing which interested me most, while the baby was in the hospital, was the hyperpyrexia, and particularly the wide and rapid fluctuations in the course of the temperature. This is something which I have never seen paralleled in any other infant. It seemed to me to be due to the fact that radiation was very imperfect and at times almost impossible, since with a comparatively small amount of bronchitis the temperature would rise in an hour or two to 108° F., and drop in the course of an hour, under the influence of a bath, nearly to normal.

"I made repeated examinations of the chest while the baby was in the hospital, but never found evidence of anything more than a generalized bronchitis of the large tubes. It was to the general malnutrition rather than to any local disease that the child's decline and final death seemed to me to be due."

Résumé.—The etiology in this case would seem to be defective intra-uterine nutrition, resulting in hydramnios, imperfectly developed skin, and premature birth. A curious fact noted by Schroeder is that over seventy-five per cent. of such infants are females. According to modern obstetricians, hydramnios may be due to a morbid condition in either mother or fœtus. There was here no history of syphilis or other disease in father or mother, they always having been in the best of health. Playfair says hydramnios is due to obstructed umbilical circulation, but the condition of placenta and cord was not noted in this case.

No microscopical examination of the skin was made, a small piece taken for this purpose being mislaid after it was in the microscopist's hands, and I was not aware of its loss until it was too late to procure another. Neuman says that the papillæ are enlarged, their blood-vessels dilated, the cutis dense, the lumen of veins narrowed by growth from their interior, the corneous layer thickened, composed of superimposed lamellæ, and the rete between the papillæ much hypertrophied. Hair follicles are absent or lengthened, and contained long hairs, the external root-sheath hypertrophied, the sebaceous glands dilated to a cyst form, the sweat-glands dilated, and the subcutaneous fat diminished. Different observers have noted slightly differing morbid conditions, but agree in the main with the above. Crocker has shown that the horny cells dip down deeper into the regions occupied in the normal skin by the rete-pegs, and that the adherent and stratified layer of each horny cap is composed at the apex of the papillary growth. The child was born without "vernix caseosa," and there was at no time any hyper-secretion of sebaceous material, so that it would be proper to classify it under the head of "simplex," as distinguished from "sebacea." The skin disease was fairly well-developed at birth, and the thickening increased as time went on, although there was a slight modification of the skin around the mouth and eyes, where it softened to a moderate extent, as shown by the gain in control over the muscles of these regions.

This child lived much longer than is usual in congenital ichthyosis, it being very exceptional to see them live more than a few days when affected to such a marked degree. The well-nourished condition and continuous growth for sixteen months also indicate an unusually good set of digestive apparatus and a large amount of vitality. The constant hyperæmic condition of the skin, the surface temperature on the three occasions when it was taken showing a rise of from two-tenths to six-tenths of a degree over that in the rectum, the axillary temperature rising from four-tenths to one degree over the rectal, is worthy of note, and it would have been interesting if these observations had been continued in the hospital. The rapid desquamation is also somewhat unusual in a simple ichthyosis, where the scales are generally adherent. It seems to me fair to infer that there was also a dermatitis present.

The extreme fluctuations of temperature from seemingly slight causes, as noted by Dr. Holt, are unequal and difficult to account for, except on his theory of imperfect radiation from the surface, though in looking over the history it has some points that make one think of a possible pneumonia or meningitis. Landois says that cutting off the cutaneous respiration in warm-blooded animals by coating with an impermeable varnish, or by destruction of skin, as in burns, causes death sooner or later, according to the extent of surface involved, probably from a loss of too much heat. It is accompanied by a fall in bodily temperature and increased frequency in respiration. Neither of these symptoms were present in this case, leaving us to infer that the insensible perspiration was about normal.

No autopsy was obtained.

THE REDUCTION OF MODERATE DEGREES OF DEFORMITY IN HIP DISEASE.[1]

By A. B. JUDSON, M.D.,

new york.

Extreme deformity occurring during the progress of hip disease is common only in patients who, for some reason or other, have failed to come under the ordinary methods of treatment. A distressing clinical picture is that of a child lying in bed with the thigh extremely flexed and adducted. But the deformity diminishes with marvellous rapidity if the weight and pulley, or any of the ordinary forms of traction apparatus is applied. These methods, while they compel a change in the direction of the limb, at the same time protect from inadvertent and painful disturbance of the joint.

The statement may seem unreasonable, but it is nevertheless true, that the more exaggerated the deformity the more easily it is affected by traction. This is due to the mechanical conditions present. An iron rod

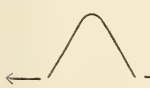

Fig. 1.

Fig. 2.

bent as in Fig. 1. may be readily straightened to a certain extent, as in Fig. 2, by traction and counter-trac-

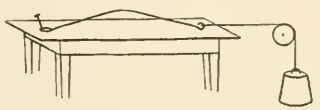

Fig. 3.

tion manually applied. Traction may then be applied by machinery, as in Fig. 3, and the rod may thus be

[1] Read before the New York County Medical Association, May 20, 1895.

still further straightened, but the straighter it becomes the more difficult it is to make any further advance, and it soon becomes evident that absolute straightness cannot be produced in a rod by traction. Another kind of force may then be employed. Pressure may be made at the convexity of the bent rod and counter-pressure at its two ends, as in Fig. 4, when the rod may be easily straightened and even bent the other way. This latter force, pressure and counter-pressure, is applicable and very effective when applied to the knee, represented in Fig. 4, in which case the leverage above and below the joint is sufficient. But there is no such

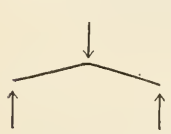

Fig. 4.

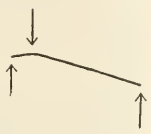

Fig. 5.

leverage found in an effort to correct in this way a deformed hip-joint represented in Fig. 5. We are reduced, then, to this, traction loses its power when the joint is partly straightened, and pressure and counter-pressure fail for the want of suitable leverage above the joint. The mechanical disadvantages thus revealed are certainly not encouraging. A ray of hope, however, is found in the reflection that the immobility is not of a hard-and-fast kind, and that, as the bad position is that which furnishes the most convenience in ordinary movements, it may be possible to accustom the patient to other habitual movements in which he will have most convenience with the limb in a good position.

I propose to give up the various theories which have been advanced to explain why the limb is flexed and adducted, and to find a simple and sufficient explanation in the proposition that the patient unconsciously assumes deformity because, when it is flexed and adducted, the disabled limb is less liable to painful disturbance and less in the way of the well limb, which now does almost all of the work of locomotion. The limb is apparently shortened (adducted) to keep it from unnecessarily touching the ground, and the appearance of lameness is increased by the action of the well foot which violates the natural rhythm, which, as we all know, is expressed thus: one—two—one—two—one—two. As the well foot hastens forward to relieve the affected foot of the weight of the body, and prolongs its stay on the ground with the same object in view, the rhythm becomes unnatural and may be expressed thus: one—two——one—two——one—two.

Now, if the patient can be induced to resume the natural rhythm, in which the time is evenly divided between the two feet, he will unconsciously surrender flexion and adduction, because in that way only is it convenient or possible for him to walk in the prescribed normal rhythm of locomotion. To put it in other words: He acquires adduction or apparent shortening because he habitually keeps the affected foot on the ground less than half the time, to the destruction of natural rhythm. If he restores the natural rhythm, and keeps the foot on the ground half the time, adduction or apparent shortening will disappear. But this cannot be done during the progress of the disease without mechanical assistance. Unsymmetrical walking is nature's conservative method of keeping the affected limb off the ground as much as possible in the act of walking, in order to avoid pressure and concussion; but with an ischiatic support which keeps the heel clear of the ground, there is no reason why the affected side, splint and all, should not come to the ground as promptly and stay on the ground as long as the well side. If the patient does this and thus lets the affected side do its share of the work, it will be found that without knowing it he is reducing his flexion and adduction and parting with the chief elements of his deformity, and this in accordance with the proposition above made, that the position of the limb in hip disease is that which affords the most comfort and convenience in habitual attitudes and movements.

We may glance at the comparative advantages of this method: 1. The permanence of the result. If the deformity is once reduced in this way all that is necessary to make the result permanent is for the patient to persist in walking in correct rhythm. If, however, a moderate deformity is reduced by forcible or operative methods, it will return if the patient maintains an unsymmetrical gait. The only exception to this would be a rare case of bony anchylosis and deformity corrected by fracture below the joint and union in a better position. 2. The early applicability of the method. Deformity may be thus reduced at the earliest stage of the disease and at the very beginning of treatment. Exceptions would be found to this in those acute periods in which the patient is averse to locomotion. 3. The late applicability of this method to patients who have recovered with deformity. Even in middle life the deformity following early hip disease may thus be reduced in an important degree.

I speak from experience when I say that by this method a great deal of the deformity attending hip disease may be removed and prevented. Success is not attained in every case, because some children can only with great difficulty be taught to walk properly, or in fact to do anything which they ought to do, especially if the parents are preoccupied or lack intelligence. But the great majority of patients are benefited in this way and readily acquire a new manner of walking, if a little of the time and attention which is given to their training in general be turned in this direction.

Progress of Medical Science.

Total Extirpation of the Rectum.—Vanderlinden and de Buck (*La Flandre Méd.*, March 7th) claim that partial resection, or even total extirpation, of the rectum for cancer is abundantly justified where at all practicable from the point of view both of its immediate and ultimate results. They record two successful cases of this kind. Case I.—A multipara, aged thirty-one, in August, 1892, gave a history of a year and a half of pain in the lower belly, constipation, difficult defecation, grooved fæces. For a year glairy mucus, blood, and yellowish fetid sanious liquid had been passed with the fæces; marked loss of appetite and body weight. Per anum a growth was felt, ulcerated in places, extending 7 ctm. from below, and invading the whole circumference of the rectum, with its greatest thickness posteriorly. The summit of the growth was easily reached, and the whole tumor could be moved downward. The operation was performed on October 30, 1892. The dorsal position was used, with the pelvis raised, and thighs strongly flexed on the abdomen. The anus was surrounded by two short incisions, which joined in front and behind. A posterior median incision was prolonged from these to the coccyx. The anal canal and rectum were dissected out as far as 3 ctm. above the growth, where section of the bowel was made. Suture of the bowel walls to the skin wound completed the operation, which lasted an hour. The patient returned home at the end of four weeks, and three months after had gained 10 kilos. in weight, and could already retain firm stools. There has been no recurrence up to the present time. The growth proved microscopically to be a lobulated epithelioma. Case II.—C. D——, aged fifty-two, married; no children. Three years' history, commencing from the climacteric, and in its details very similar to Case I. Two indurated ulcerated masses were found in the anal region. The rectum was in-

vaded in its whole girth by a soft, yielding, easily bleeding tumor, whose summit was reached with difficulty 10 to 11 ctm. above the anus. Operation February 24, 1895. Left lateral position, thighs strongly flexed and pelvis raised. The incision ran from two fingers' breadth below the posterior superior iliac spine along the groove between the gluteus maximus and sacrum toward the median line as far as the summit of the coccyx, then surrounding the anus. The musculature of the buttock was detached, the insertions of the great and small sacro-sciatic ligaments cut, and the coccyx extirpated. A part of the left side of the sacrum was removed, the abundant bleeding controlled, and the rectum isolated, commencing with the anal aperture. The peritoneum was opened after isolation of the anterior rectal wall. The bowel was cut transversely 2 ctm. above the growth, and its end, slightly twisted on its axis, was sutured to the borders of the skin wound. The operation lasted an hour and three-quarters, much blood being lost. A large quantity of NaCl solution was therefore injected, and, except for two days' fever, the patient did well, and at the date of report was convalescent.—*British Medical Journal.*

The Microbiology of Acute Peritonitis.—Courtois-Suffit, in his recent monograph on "Diseases of the Peritoneum," classes first in order among the pathogenic microbes in peritoneal inflammations the bacillus coli communis (*The Boston Medical and Surgical Journal*). This micro-organism is a facultative anaerobic, a normal inhabitant of the intestines, but pathogenic under morbid conditions such as occur in all kinds of peritonitis of intestinal origin. Its presence has long been recognized in peritoneal exudations, while it is constantly found in septic peritonitis following intestinal wounds, perforating (gastric, typhoid, enteric, appendicular) ulcers, ischio-rectal abscess, cancer of the colon, hernia, thrombosis of the mesenteric vessels, etc. It has been affirmed that under certain circumstances, as when disordered circulation, strangulation, extreme fecal distention, undue pressure, or mechanical injury has impaired the integrity of the bowel and lowered tissue-resistance, this bacterium may become migratory, gain the peritoneum, and excite inflammation. Cornil found such bacteria actually in the substance of the wall of a partly necrosed intestine. The possibility of such migration may explain many cases of so-called idiopathic peritonitis attending stercoral impaction, severe bowel inflammations, etc.; the germs passed through the intestinal walls and provoked peritonitis. It is doubtful if peritonitis has ever followed cystitis, yet Achard and Renaut have proved the identity of the colon-bacillus with the bacterium pyogenes of the bladder. The pneumococcus has very rarely any causal relation to acute peritonitis, whether the infection occur as a sequel to pneumonia or independently of that disease. The streptococcus pyogenes has been found in the pus of a great many cases of peritonitis, where it existed to the exclusion of every other micro-organism (post-operative and puerperal peritonitis). Cases of streptococcus-peritonitis following erysipelas of the face have been reported by Cheurlin and others, and in rare instances this disease has succeeded scarlet fever, a malady in which the streptococcus seems to have a predominant part. Penetration, by the microbes, of the abdominal wall is said in rare instances to have taken place in cases of erysipelas of the abdominal integument; and puerperal peritonitis from extension of a streptococcus-inflammation from the pelvic peritoneum and uterine cavity is of very common occurrence. Acute peritonitis has been in numerous instances ascribed to the staphylococcus (aureus and albus) found apart from other micro-organisms in the pus. In other cases, the staphylococcus was associated with the streptococcus, or with the rod-shaped or round micro-organisms of putrefaction. The saprogenous microbes seem to have been influential in certain cases. The colon-bacillus is probably a bacterium of saprogenous character, with possibilities of greatly exalted virulence. Suppurative salpingitis is a recognized cause of acute peritonitis. When the salpingitis has developed under the influence of the true pyogenic organisms (streptococci and staphylococci), a generalized peritonitis which is almost always fatal follows the rupture of the tube. The case is not so serious, according to Bumm, when the salpingitis succeeds gonorrhœal infection, and in which the exudates contain only the diplococcus of Neisser. The latter micro-organism, Bumm says, can exert its action only on mucous membranes, being inoffensive to the serosa and cellular tissue. Naturally, then, the rupture of such a pus tube, or the leakage of pus from the fimbriated end into the peritoneum, would not be followed by a general septic peritonitis, but the exudate would be resorbed like any aseptic fluid. With regard to the effect on the peritoneum of rupture of one of the hollow organs of the abdomen, the result, as Courtois-Suffit remarks, is variable, depending on the presence or absence of microbes in the extravasated fluid. The bursting of the healthy bladder with effusion of normal urine into the peritoneal cavity is not followed by acute peritonitis. This has been proved by the experiments of Gosselin, Robin, Albarran, and others. The case is altogether different when the urinary passages are infected and the urine contains the streptococcus pyogenes, the septic bacterium of Clado, or other pyogenic organisms.

What is true for the urine is equally exact for the bile, as abundant experiments on animals have shown. This is made plain by Dupré in his now classic work on "The Biliary Infections." But the biliary passages and the bile may become infected from various causes, and rupture of the gall-bladder would then be followed by a fatal peritonitis. A case of this kind has been reported by Fränkel, who found in the peritoneal exudate streptococci and staphylococci.

Penetrating wounds of the stomach, allowing small quantities of gastric juice and other contents to escape into the peritoneal cavity, are not necessarily fatal if the wound be not large and the leakage not great. The stomach is not a good culture-field for pathogenic microbes, the gastric juice being aseptic and antiseptic. The result of a penetrating wound of the stomach or a perforating ulcer will, of course, be far graver if the stomach or its secretions has become pathologically altered, and if there be considerable escape of its contents into the peritoneum.

When the intestine is the source of the peritoneal lesion, whether by traumatism or profound ulceration, the peritonitis is likely to be spreading and fatal, especially if there be a massive infection. The microbes which are chiefly concerned are those which are found in a normal state in the intestine: the coli communis, the bacillus albuminis, the bacillus mesentericus vulgatus, the septic vibrio of Pasteur. There is a law laid down by Malvoz, which, as far as it is accurate, may be of help from a medico-legal point of view. If the peritonitis be of intestinal origin, the bacterium coli will show it; if it be of uterine origin (as when consecutive to abortion), the presence of the streptococcus will prove this, even though there should be no visible inflammatory lesions of the genital organs.

The Pathology of the Pancreas.—It is only within comparatively recent years that any notable additions have been made to our knowledge of the pathology of diseases of the pancreas. A decided impetus was given to the subject by the researches of Fitz, who practically established upon a firm clinical basis the symptomatology and diagnosis of acute pancreatitis and allied conditions. Of the etiology of these we practically know nothing, and this line of reseach affords a field for investigation that promises to yield important and interesting results (*Medical News*). Recent clinical

and experimental observations have shown that some lesions of the pancreas are attended with glycosuria, but an even more obscure association is that with the peculiar condition known as fat-necrosis. While this has been observed most commonly in connection with pancreatic disease, it has also been found in some cases in which such disease could not be demonstrated. An interesting contribution to this subject has recently been made by Hildebrand, who, in a series of experimental observations on cats, succeeded in inducing fat-necrosis by ligation of the pancreas or its vessels, and by transplantation of the organ in whole or in part. In two animals the pancreas alone was ligated ; in six others ligatures were also applied to all of the veins. Sugar was found in the urine of one of these. In one instance a bit of pancreas, two by three centimetres, was excised from the continuity of the organ and fixed with a suture in the omentum of another animal ; and, again, an entire pancreas was treated in the same way. In another experiment a whole pancreas was scarified and made to surround a portion of the small intestine. The animals withstood the operations well, but in all the characteristic white areas of fat-necrosis appeared in the peritoneum comparable to that observed in man.

Growing Pains.—Growing pains, defined as pains in the limbs caused by and during rapid growth, and sometimes so severe as to give rise to growing fever, have been diagnosed by the author less and less frequently as the years rolled by, until the vanishing point was reached. Cases which have been classed together under this name are the following :

Myalgia from Fatigue.—This is the commonest variety, usually about the knees and ankles after unusual exertion. They are probably due to autoinfection brought about by excessive production of *effete* materials in the blood and their inefficient elimination. Elevating the limbs and rubbing with the palm of the hand in a direction toward the heart, relieving venous stasis and facilitating a supply of healthy blood to the exhausted muscles, promptly relieves the pain.

Rheumatism.—This is second, if not first, in frequency. There is slight pain in the joints, little or no swelling, and very mild fever, and hence the true cause is not recognized ; but rheumatic endocarditis frequently develops in these cases.

Diseases of Joints and Bones of the Lower Extremities.—Cases of hip-joint disease and suppurative epiphysitis of the upper end of the fibula, diagnosed by the laity and allowed to go on untreated, are related under this heading.

Fevers, accompanied by pains in the limbs, in one instance proving to be inception of typhoid fever, constitute this class.

Adenitis.—Here, again, the mother still supposes that the lad of sixteen years suffered from "growing pains," but he was treated for gonorrhœa and a sympathetic bubo. The malady "growing pains," with its frequent concomitant growing fever, like its congener disorders of dentition, as a separate morbid entity exists principally as an article of faith. The complaint still maintains, however, a strong hold of the lay mind, and forms an extremely common lay diagnosis which is often the cause of much suffering, and even death, by leading to the neglect of curative measures at a time when they are most effective.—*Archives of Pediatrics.*

Chronic Lacunar Tonsillitis.—Dr. Ball holds that the essential cause of this disease is some narrowing of the lacunar tract or orifice impeding the free egress of the contents, together with an abnormally free desquamation of the epithelial cells. The cheesy masses are mainly composed of these elements more or less altered. The epithelial cells are arranged in layers, those on the outer surface, and therefore most recently shed, being the least altered. A certain proportion of leucocytes is present, but rarely in any number. Toward the central part of the plug especially are found fatty particles and cholesterine. Leptothrix filaments and various other micro-organisms are also found in abundance. The functional troubles bear relation to the nervous irritability of the individual. Pain is a common symptom. This often radiates toward the ears, and is apt to be felt more especially when swallowing saliva, and less when swallowing food. Troublesome coughing fits may be present, especially in the morning. The breath has a slightly fetid odor, and the cheesy masses at times attract the attention of the patient. On examining the throat, the tonsils are usually found enlarged ; often there are adhesions between the tonsil and the anterior pillar concealing the tonsil from view. In some cases it may be necessary to retract the pillar or to examine the posterior or upper part of the tonsil with the rhinoscopic mirror. Sometimes a careful search will fail to discover any concretion in the lacunar orifices. In this case pressure with the tongue-depressor, or the introduction of a probe into a lacuna, may bring to view one of these chessy masses. When the tonsils are small, there are two points which should be particularly explored—namely, a large crypt, the orifice of which is covered by the anterior pillar, and the upper extremity of the tonsil between the pillars. the region of the epitonsillar fossa. The cheesy plugs will be found to be easily removed by means of a probe or spud passed into the crypt. Subacute exacerbations of the symptoms occur from time to time, lasting two or three days or longer, and causing general malaise, more marked throat-pains, otalgia, and pain on eating and speaking.

The author holds that the most rational and effective treatment is opening up the crypts by free division of the crypt-walls. This is best accomplished by a hook-shaped blade fixed at right angles to the handle. The point of the knife is blunt, but sufficiently fine to allow of its insertion into the smallest cryptic orifice. The method of procedure is as follows : The operator sits in front of the patient and throws a good light into the throat by means of the ordinary forehead reflector. The tonsil to be operated upon is anæsthetized by the application of a ten or twenty per cent. solution of cocaine. This, however, is by no means necessary, as the operation is not really painful. The tongue being depressed with a spatula, the point of the instrument is inserted into one of the cryptic orifices and is brought out at a neighboring orifice, or, if necessary, it is forced through the tissue. The intervening tonsil tissue is then cut through, and this can usually be effected by simple rotation of the handle of the instrument. In this way several crypts can be opened up at a sitting and any cheesy masses that may be present are evacuated. The bleeding is never considerable. Sometimes, especially if the tonsil operated on is large, there will be left some loose tags of tissue, which should be trimmed off with a pair of curved scissors. Adhesions between the tonsils and faucial pillars can be divided in the same manner as the crypt-walls. From two to three sittings, or even more, may be required for each tonsil, and a week may be allowed to elapse between each sitting. To diminish the tendency of the cut surfaces to unite, a strong solution of iodine (iodine, 90 grains ; iodide of potassium, 90 grains ; water, 1 ounce) should be applied at the termination of each sitting. In any case this is a good antiseptic application and should never be omitted. A little soreness may be felt after the operation, but this never continues more than a day. A boric-acid gargle may be used during the intervals between the sittings.—*The Practitioner.*

An Early Instance of the Bath Treatment of Typhoid Fever.—Pope Leo XIII., when a young man residing in Benevento, suffered from typhoid fever, and was treated by Dr. Vulpe by means of cold baths. That was fifty years ago.

There is a Duty of Fifty Per Cent. ad Valorem on diphtheritic antitoxin imported into Canada.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street

New York, July 6, 1895.

THE ENLARGEMENT OF THE MEDICAL RECORD.

WE are again called to do a pleasant duty to our readers and contributors. The MEDICAL RECORD has grown so steadily in the capacity and worth of its material that it has been deemed advisable to increase still further the number of its pages and to enlarge correspondingly its capacity for usefulness to its subscribers, contributors, and advertisers. With the commencement of the present volume there will be an increase of *four extra pages to each issue*, making an aggregate addition for the year of over four hundred double columns, an equivalent in their turn to an ordinary-sized octavo of nearly eight hundred pages, *with no increase of cost to its subscribers.*

In view of this fact the conviction must continue to force itself upon every one that such a course is warranted by a success unprecedented not only in American medical journalism, but, we believe, in the world. It must also be evident, judging from these tangible and uncontrovertible evidences of success, that the end has been gained by a wide-spread appreciation of our policy of independence, fairness, and enterprise.

It will be our aim, with the increased facilities at our command and the liberal and expansive purpose of compassing a still larger field, to make the MEDICAL RECORD more than ever a thoroughly cosmopolitan journal, in which not only the interests of the great medical centre are represented but those of the entire country are duly and impartially considered.

Numerous changes will be made in the course of the year to realize this policy, and no pains nor expense will be spared to make it still more representative of the practical needs of the profession of the entire country. We will thus strive to give a metropolitan journal a thoroughly cosmopolitan scope, being only systematized in its efforts by the convenience and necessity of an actively working focal centre. In following such a course there is no intention of interfering with or militating against the interests of local journalism in near or far-off districts; such periodicals have functions of their own, and their proper fulfilment is as necessary and as important as those that apply to the larger publications. The wide-awake practitioner must be informed of the doings of his local societies and of all matters within the direct touch of his individual work, and must necessarily leave the consideration of wider interests to the larger and more widely circulated metropolitan weeklies. Each journal has its place, and each, to do its work faithfully, supplements and amplifies that of the other. We believe in local journals as well as cosmopolitan ones. They have a common interest, only the lines of usefulness stretch in different directions.

Thus we can help each other on the broad principle of a generous rivalry in the common cause, and in the ultimately laudable aim of advancing the interests of the profession and promoting that active dissemination of scientific truths which makes medicine the most progressive of all the sciences.

THE PRESENT MEDICAL LAW OF NEW YORK.

ELSEWHERE we publish a full text of the medical law of the State. Some day, perhaps, the few familiar with the struggle involved in securing these legislative enactments, now compiled in one law, will relate the history of the conquest. In the near future we propose to call attention to some of the more important features of the law's requirements. Of course the general theory of the law is that the State should be the final adjudicator of the credentials presented by those who desire to practise medicine within its borders. The M.D. degree has thus ceased to be anything more than an honorary title conferred by a private corporation. Although it is true that no one without it can be admitted to the State licensing examination, the supreme test of ability to practise is now vested in the State, which in turn delegates its power to twenty-one examiners (seven from each of the incorporated State Medical Societies) who are sworn to do their duty as State officials.

Under paragraph 148 of the law licenses conferred by other State examining boards may be indorsed by our State regents, but the standards of these other State boards must not be "lower than those provided by this article." Because of these quoted lines no license from a sister State has yet been indorsed, as no other State meets the standard of our preliminary requirements. It would be manifestly unfair to our own State medical colleges, and would constitute an unjust discrimination against our own students, were we to enforce No. 5 of paragraph 145, and in turn permit licentiates of other boards, no matter how severe the medical tests, to register in our State without having submitted to the same or to similar preliminary academic tests. Our New York medical colleges may for a time lose students because of the prohibitive features of paragraph 145; but in the long run this advance of standard will redound to their financial status, as it now advertises their determination to build up medical colleges of which the citizens may be proud and their graduates boastful. The effect of the recent medical laws thus far has been to drive incompetent doctors from our doors, to prolong courses of medical study, to add new studies to the curriculum, and to elevate the tone of the profession as well as to improve its *personnel.* Thus it will be seen that much has been accomplished, but until the average longevity is increased, and the average mortality of the community is decreased, the

full measure of the law's beneficence will not be apparent to the laity nor will it be satisfactory to the profession.

IS CHOLERA ENDEMIC IN EUROPE?

Certain alarmists, moved by the regularly recurring reports of the ravages of cholera in Europe, especially in Russia and the eastern provinces of Austria and Prussia, each summer, have asserted that the disease has established for itself another nidus, outside of India, whence it may make irruptions into Western Europe. It is true that nearly every summer during the past ten years there have been outbreaks of cholera in some parts of the continent of Europe, in Spain, Italy, France, Germany, Russia, and Turkey, but many of these have been local and traceable to very differing sources. There have, indeed, been two distinct epidemics during this period, one around the shores of the Mediterranean, spreading inland to a slight extent, the other taking the ordinary course across central Asia, entering Europe through southern Russia.

If we look back over the successive epidemics of cholera that have passed over Europe, we shall see that most of them lasted several years, though varying in intensity and in the locality of greatest prevalence. The first appearance of cholera in Europe was in 1823, when it invaded southern Russia. This outbreak was of short duration, and nothing more was seen of the disease until six years later, when it reappeared in the Russian province of Astrakhan. This time it did not remain confined to the shores of the Caspian, but spread throughout Russia, invaded the rest of continental Europe, reached England two years later, and crossed the ocean the following year. Every country in Europe and North America, with the exception of Greece and Switzerland, suffered from the ravages of the disease. The epidemic did not finally die out until 1837. Since then there have been epidemics of larger or shorter duration in 1846, 1865, and 1884. The third epidemic persisted for ten years, from 1846 to 1855, the fourth for nine years, or until 1873. The present epidemic has existed in Russia only since 1892, so that this is its fourth summer in that country. As three of the former epidemics lasted eight, nine, and ten years, respectively, it seems rather premature, at the beginning of the fourth year of this visitation, to cry out that the disease is no longer epidemic but endemic, and that it has found a new home far from the Ganges on the banks of the Vistula and about the shores of the Caspian Sea.

PROGRESS OF SERUM-THERAPY AND ORGAN-THERAPY.

A short time ago Drs. Emmerich and Scholl reported some favorable experiments with the use of the erysipelas serum in the treatment of cancer. A few weeks after this report Dr. Bruns published a criticism denying the alleged improvement in the cases. Still later Dr. Angerer, of Munich, has reported some cases of cancer of the breast treated with erysipelas serum without any good effects. Drs. Richet and Hericourt recently published the account of a case of osteo-sarcoma of the leg which they treated with injections of serum. The result in this case, as well as in another case of fibro-sarcoma of the breast, was so brilliant that the doctors are questioning now whether or not they did not make a mistake in diagnosis.

The most curious perversion, if we may call it so, of serum-therapeutics is that in which the serum of horses, which are supposed to be immune against tuberculosis, is used in the treatment of tuberculosis in human beings. Dr. Paquin, of St. Louis, is responsible for this extremely unique method of applying the immunizing injections. He reports twenty-two cases of tuberculosis in which patients were treated with this serum with more or less favorable results. His statistics were not very encouraging, and the theory on which his treatment is based, if it can be called such, has no rational basis whatever. While there may be certain animals who are immune to tuberculosis, there is nothing in medicine to show that in human beings an attack of tuberculosis produces immunity in the slightest degree.

Syphilis has also reached the stage of serum-therapeutics. Dr. Richet communicated in April last to the Society of Biology a report of the case of a woman who had suffered for three and a half years with multiple ulcerating gummata. She was injected with the anti-syphilitic serum and in fourteen days was well! This serum was obtained from a donkey who had fifty-four days before been injected with the blood-serum of a syphilitic in the secondary stage. Gilbert and Fournier have collected the work of other experimenters in this same line, and they detail the methods and results of some new experiments which they have themselves undertaken in the treatment of syphilis with the serum of immune animals and men. The practical results are as yet very slight.

More recent reports upon the value of the serum-therapy of diphtheria continue to be favorable, and there has nothing yet appeared in current literature to justify us in doubting that this treatment will continue to prove a valuable help in our fight with this serious disease.

Closely related to serum-therapy is what is now generally termed organ-therapy, or treatment with organic extracts. Dr. Drummond, in the *British Medical Journal* of May 18th, reports the case of a woman seventy-three years old, who was suffering from what appeared to be pernicious anæmia. She had only seven hundred thousand red blood-cells to the cubic centimetre. Under the use of bone-marrow given in milk she improved very rapidly.

Dr. Walter Clark reports a case of diabetes insipidus in which the patient was treated with extracts of the suprarenal capsules. The patient was a woman thirty-nine years old, who had been for a long time under observation, and who was passing about four gallons of urine daily. Under the use of the suprarenal-capsule feeding the urine was reduced in amount to about three pints daily and its specific gravity increased from 1.005 to 1.009. As soon as the use of the suprarenals was stopped the symptoms began to return.

Dr. Byrom Bramwell, in the *British Medical Journal* of June 1st, reports a case of tetany treated with thyroid extract. The patient was a boy eight years old, and the disease began in the fall of 1893. During

the winter and spring of 1893 and 1894 he was under treatment by Dr. Bramwell with some improvement. In March, 1895, he was placed upon thyroid extract. After three weeks his attending physician stated that the improvement was something phenomenal, and five weeks later he writes that the case continued to improve in every way.

THE PLETHORA OF MEDICAL SOCIETIES.

Both Paris and London are suffering from a plethora of medical societies. This is the statement made by Dr. Morris in *The Practitioner*, and it is confirmed by the comments of Parisian and London contemporaries. The remedy suggested, of course, is that some of the societies amalgamate. We have no doubt that the advice is excellent. It has often been tendered to the medical men of New York, where societies are also extremely numerous, but the advice does not seem to be taken. Societies go on multiplying in New York and everywhere else ; and we take it that it must be because there is some actual need for them. In this city the problem has been pretty well solved by the success of our Academy of Medicine. In this organization there are so many and such excellent opportunities for societies of specialists to organize under the fostering wing of the Academy that we do not recall any new organization since the sections of the Academy were fairly started. New societies continue to spring up, but they are general in character and have for their excuse social and local causes rather than scientific. They fulfil their purpose in enabling the medical men in certain parts of the town to get together and become acquainted with each other, and in this way they do very good work.

REFORM IN INTERNATIONAL CONGRESSES.

Now that the majority of the annual meetings of our State and International Medical Associations are over, a criticism upon these meetings by Dr. Pistor, in the *Quarterly Journal of Public Health*, may seem very timely. Dr. Pistor thinks that there are too many formal dinners, too many evening parties, and too many invitations to visit industrial establishments, hospitals, factories, orphan asylums, and so on. He asserts that all these interesting functions should be entirely done away with, and that visitors who desire to live sumptuously should do it at their own expense. Many cities in Europe, he says, are unwilling to receive international congresses on account of the heavy expense connected with them. This is not the case, we may say, parenthetically, in the United States, but then we have not the thrifty habits of the older countries. Another trouble with these congresses is that there are too many papers announced to be read, and the discussions, he thinks, are on this account usually very unsatisfactory. The number of sections also should be limited. In fact, Dr. Pistor enumerates all the well-known and well-worn criticisms upon the conduct of the medical congresses of the present day. The defect in Dr. Pistor's position is that he expects too much of this imperfect world. Medical congresses are not meant solely for the production, or even the exploitation of great scientific truths, but rather for the personal benefit that is produced by the contact of men from different parts of the world with each other. It is at dinners and at the various other reunions and festivities that visitors to congresses really learn the most. Dr. Pistor, when he gets older and has had more experience with congresses, will probably acknowledge the truth of this statement.

THE STATE AND LOCAL CHARITIES.

The State of Pennsylvania has always been peculiar in its relations to medical charities. Unlike most other States, it has often and generously appropriated the funds of the taxpayers from all over the State to the promotion of local medical interests. *The Medical and Surgical Reporter* furnishes a list of the appropriations as reported by the Appropriation Committee at the present session of the Pennsylvania State Legislature. These include sums of $150,000 to the Medico-Chirurgical Hospital, $200,000 to the University of Pennsylvania, $55,000 more to the hospital of that university, $112,000 to Jefferson Medical College, $8,000 to the Woman's Hospital, $3,000 to the Samaritan Hospital, $4,000 to the Children's Hospital, and $25,000 to the Gynecean Hospital. Of course, if the hospitals of Philadelphia get State appropriations the hospitals of the smaller cities must also have their share, and we find a list of forty different hospitals scattered throughout the State, to each of which an appropriation is given. If the general principle of State help to local institutions is considered by Pennsylvania economists to be a sound one, no objection can be raised against any such widely extended generosity as that which the Pennsylvania Legislature shows ; but it seems to us that the State will find itself eventually in a very embarrassing situation if it continues the policy which it has adopted of helping along almost any private medical institution just because it has a medical charity annex.

News of the Week.

The Brain of Buchanan, the murderer, executed July 1st, is said to have weighed only thirty-one ounces. He was a small man.

The Heaviest Woman in America died at Millersburg, O., on July 1st. Her weight was 675 pounds.

The Woman's Medical College of Cincinnati, O., has united itself with the Laura Memorial Medical College. There did not seem to be room enough in Cincinnati for two medical colleges for women.

Doctors and Athletics.—The medical profession has its full share of athletic honors. Dr. Grace has proved himself the champion cricket-player of England, and therefore of the world, and Dr. Pym, of Ireland, having beaten all the tennis experts of Great Britain, has come over to this country and done the same to the American tennis-players. We have in this city Dr. Hammond, who is the champion at foils and broadswords of the United States, and doubtless there is rich material for a bicycle champion among the numerous medical men who have taken up that pastime.

The Galactogogues.—Dr. Grinewitch has been making a study of the drugs which increase the flow of milk without in any way injuring the quality of it. He finds that the most efficient of them is a plant which is practically unknown in medicine, the common goat's rue (*Galega officinalis*). He gives a drachm of the tincture about five times a day. The next drug in the scale is the common stinging nettle, of which he gives from two hundred and fifty to five hundred drops of the tincture daily.

The Thyroid Treatment of Tetany.—We referred to the successful treatment of tetany by thyroid feeding a short time ago. Since then Dr. Bramwell refers to certain experiments made by Dr. Gottstein, in which he had success by grafting the thyroid in a case of tetany. Dr. John Thompson, however, states that he has used the thyroid in tetany without any success.

The Meeting of Bacteriologists, held in this city June 21st, resulted in the appointment of a committee to consider both the papers presented and the discussion that followed, and to make a report to the American Health Association as to the most desirable methods to be observed to secure the greatest uniformity in the results of the bacteriological examination of water. The names of this committee are: Professor W. H. Welch, M.D., chairman; Professor W. Sedgwick, Ph.D.; Professor Theobald Smith, M.D.; Professor T. M. Prudden, M.D.; Professor J. G. Adami, M.D.; George W. Fuller, S.B.; Professor A. C. Abbott, M.D.; Professor V. A. Moore, B.A., M.D.

Bequests to St. Luke's Hospital.—By the will of the late Rufus Waterhouse the bulk of his estate, amounting to about two hundred thousand dollars, is left to St. Luke's Hospital for the purpose of establishing and maintaining the "Mary S. Waterhouse Memorial Ward" for consumptive sewing-women or consumptives dependent upon sewing-women.

Dartmouth Medical College.—By vote of the Trustees it has been decided to raise the standard of admission to the college.

Meetings of Societies.—The Sixty-third Annual Meeting of the British Medical Association will be held in London on Tuesday, Wednesday, Thursday, and Friday, July 30th to August 2d, Dr. E. Long Fox presiding. The meeting promises to be an unusually large one, owing to the choice of the place in which it is to be held, and a large number of American physicians will be present. Sir William Broadbent delivers the Address on Medicine, and Mr. Jonathan Hutchinson that on Surgery. In the Section on Medicine there are to be discussions on diphtheria, on pneumonia, and on the causes of acute rheumatism. In the Section on Surgery there are to be discussions on fractures of the upper third part of the femur, and on the surgical treatment of cysts, tumors, and cancer of the thyroid gland. There will be on the first day a reception at the Imperial Institute in the evening, following the President's address, and on the third day there will be a dinner at Langham Place.—The American Academy of Railway Surgeons will meet in Chicago on September 25th, 26th, and 27th.—The Third International Congress of Physiologists.—The Third International Congress of Physiologists will be held in September, 1895, from the 10th to the 14th of the month, at Bern, Switzerland.

New Medical Law for Delaware.—The Governor of Delaware, acting under the medical law passed by that State, has appointed two Boards of Examiners, one to represent each of the chief schools of medicine. The law provides that the Chief Justice and the Chairman of each Board shall constitute a Council of Medicine empowered to issue licenses to persons that have passed the required examination. The law provides a fine of $500 or not more than one year's imprisonment for persons convicted of practising without a license. The new Boards of Examiners will meet the first week in July to organize, and the Council of Medicine will then be constituted. Thereafter newcomers must submit to examination.

Obituary Notes.—Dr. Henry D. Hall died at Jamaica, L. I., July 1st. He was born in Clinton County eighty-seven years ago. He was Assistant Surgeon in the United States Army during the war, and for a number of years practised his profession at Glen Cove, L. I.—Dr. Ezra Graves, a prominent physician of Amsterdam, N. Y., died on June 30th. He was fifty-six years old. He had served as coroner of Montgomery County, and also as city physician of Amsterdam. He was a graduate of the Buffalo Medical College.—Dr. J. B. Wilbur, formerly a well-known Brooklyn practitioner, died at Montclair, N. J., recently, aged seventy. He was a graduate of Harvard College and Harvard Medical School, and served as surgeon of a Massachusetts regiment during the war.

The New Health Commissioner.—Dr. George B. Fowler has been appointed Health Commissioner of this city in place of Dr. Cyrus Edson, resigned. Dr. Fowler is a native of Alabama, but came to this city during the war, and graduated from the College of Physicians and Surgeons in 1871. Dr. Fowler is a well-known and very popular member of the profession of this city, and his appointment will give pleasure to his very large circle of friends. Dr. Edson's career as a member of the City Board of Health was most creditable to him, and he retires with a reputation of the highest kind as a sanitary and executive officer.

Monument to Dr. Guerin.—The friends of the late Dr. A. Guerin have raised sufficient money to erect a statue to him in his native city.

Doctors' Bills.—The Chicago *Tribune* publishes an account of an interview with a member of a firm in that city whose business consists entirely in the collection of doctors' bills. He was asked if the majority of patients paid their accounts, and said that they did not. From this it would be inferred that in Chicago over one-half of the patients failed to pay their doctors' fees—a statement that is extraordinary and improbable. We believe that in most American cities from seventy to eighty per cent. of the fees charged are paid and collected, and probably a larger percentage would be obtained if doctors rendered better service or managed the business side of their profession in a more rational manner.

Clinical Department.

CASES SIMULATING TYPHUS FEVER.

By S. DANA HUBBARD, M.D.,

NEW YORK.

THE following histories of two very interesting cases came under my observation while at the Riverside Hospital, and I deem them worthy of record :

CASE I.—A. T——, German ; married ; thirty years of age ; laborer ; residence, New York City. Habits : Alcoholic, vagabond ; family history not obtainable ; past history not obtainable. Present history : As perfect as could be obtained, was to the effect that having "cold and cough" went to a dispensary for medicine, and here they said he had measles, which was confirmed by the diagnostician of the Health Department, and in the course of events he was transferred to North Brother Island, where he came under my observation.

On admission he had a general bronchitis, with suffused eyes and watery discharge from nose, and an eruption over entire trunk, face, and extremities—the eruption consisting of large, multiform, coalescent blotches, with curvilinear borders crescentically arranged and of a deep pinkish red color. His face in addition was much swollen. His temperature was 105⅕° F. ; pulse, 100 ; respiration, 28. Patient was slightly delirious. Stimulants, antipyretics, and enema were ordered. At 7 P.M. the temperature had fallen to 102⅕° F., and patient was resting easy. During the night the patient was restless, though delirum had disappeared.

October 13th.—Diarrhœa set in and continued in spite of treatment. Pulse irregular and compressible. Patient sighing and has gloomy forebodings.

October 14th.—Temperature elevated and persists above 102° F., in spite of antipyretics and cold packs. Patient apparently losing ground rapidly. Stimulants pushed without effect. Pulse very weak and irregular. Patient very delirious. Eruption fading and I considered him improving as regard his measles ; but what underlying condition was causing all this constitutional disturbance I was at a loss to explain. Consultations were held and a change of diagnosis was made from measles to typhus fever, I disagreed, but was willing to use all precautions and accordingly the patient was isolated and observed just as if it were a *bona fide* case of typhus.

Here was a man, a tramp, filthy, unkempt, coming from a lodging-house (where we got nearly all of the second epidemic of typhus cases), having a purplish (for the rash was now fading), mottled eruption, with high temperature (persistent), congested eyes, contracted pupils, with a dull, listless expression, and a delirium of a talkative character.

Surely one would be justified in diagnosing typhus in a case of this kind if we had no history previous to this examination ; and we had, for on the 12th it was as clear a case of measles as one would wish to see ; but on the 14th it most assuredly resembled a typical case of typhus fever.

On the 15th, as the patient was sinking, the darkness of our difficulties grew deeper, but with the morning the star of clearer vision began to rise, and when the brightness of the day shone our mysteries were fading as fast as the dew before the summer's sun, for at 5 P.M. the patient began to vomit, the ejecta being of a bright red color streaked with a darker red, and clotted and lumpy. He was examined quickly to find the source of this ejecta. The lungs showed nothing and the stomach was empty. More trouble. The dark blood, no doubt, came from the stomach ; but had it not come from another source, been swallowed and then ejected ? Acting on this theory and believing myself sufficiently clear, I diagnosed hemorrhage from the alimentary tract between the stomach and mouth ; but where ? I still felt uncertain about the lungs and examined again, when lo ! the stomach was partly filled. Had I not an hour and a half ago examined him and found this organ empty, and now it was partly filled ? No food (fluid) had been given, and he had not swallowed any, for I watched him to see if he would bleed from the lungs, and if it would come up the trachea and then go down the œsophagus, and I found the trachea clear. Treatment was accordingly given for hemorrhage from the stomach, but after repeated vomiting the patient finally sank rapidly, dying in convulsions at 9 A.M. on October 16th. At 5 A.M. on the 16th his temperature rose up to 108° F. (rectal), but declined gradually to 102½° F. (rectal) when he died.

Autopsy.—Evidences in general of an acute infectious process, and in addition the stomach and entire intestines to within three inches of caput coli, where it terminated abruptly, were filled with a dark grumous mass, apparently clotted blood.

At the lower end of the œsophagus was found the cause of all this hemorrhage. There were three lineal ulcers of varying length, arranged in a circular manner around the lower opening ; the largest ulcer being about an inch and a quarter long and its depth extending through to the outer coat of the œsophagus. This latter one evidently was the cause of all this hemorrhage and of the fatal termination, for it had eroded an artery.

Owing to the peculiar shape and position of these ulcers one might suppose them to have been traumatic, as caused by sword-swallowing, though this could not be verified.

CASE II.—Michael N——, aged twenty-three ; Ireland. No history. This case occurred during the epidemic of typhus fever in 1892–93, and is one of interest in many ways. The case on admission was delirious and the previous history could not be obtained. Here was a young man, a blonde, of an alcoholic, vagabondic appearance, filthy and unkempt, ill with a high temperature—105° F. (rectal)—delirious, with a general mottled eruption. The case occurred during the prevalence of typhus fever in this class of citizens.

The case was diagnosed as typhus by the Health Department diagnosticians, and passed as such by both the resident physicians of the Reception Hospital and of the Riverside Hospital. Accordingly the case was transferred to the typhus ward and treated as such.

Attention was now called to this patient, and I was informed that if this was a case of typhus then the place from whence he came (which was a lodging-house) was a new centre of infection, and wanting to be more certain than in a general routine way I visited the case again, examined him more carefully, with this result :

A young man, blonde, body fairly well nourished, with a delirium of low type, with features pinched and face cyanotic ; sordes abundant, tongue dry, coated, hard, and cracked. Eyes : Conjunctivæ normal, rather "glassy," with pupils dilated if changed at all ; subsultus tendinum, and carphologia present, and patient tossing, in bed. His skin was dry and hot, and another interesting condition was the eruption, which was all over trunk, anteriorly and posteriorly, upper and lower extremities, and a few spots on forehead. The eruption was of a mottled, macular character and flat, disappearing on pressure, and color deeper than pink and lighter than chocolate. The macules were numerous and the mottling slight, but easily distinguished on account of his fair skin. His abdomen was tympanitic, pressure gently exercised caused no evidence of pain.

An enema was given as was usual, and a movement, partly formed, brown and odorous, was the result. Urine : Nothing special. Not examined microscopically. Antipyretics, sedatives, and stimulants ordered, and spots marked out as best as was possible.

July 11th.—Patient semi-unconscious, takes nourish-

ment and medicines. No change in his condition or eruption, constipated, and voided very little urine.

July 12th.—Bowels moved once, partly formed, brown and odorous. Temperature continues high, subsultus and carphologia absent. Patient restful and very weak. Pulse very rapid and compressible. Has difficulty in swallowing. Tympanites still present, though not so marked. Spots looked out for as well as possible, and no new ones found, therefore no crops. Eruption brownish and apparently fading.

July 13th.—Patient at 1 A.M. had temperature 105 $\frac{2}{5}$ F., and was failing rapidly, and at 3.30 A.M. he died.

Autopsy.—Beyond the evidences of an acute infectious process we found several ulcers, some very large. The presence of these undoubtedly clear the diagnosis.

This case is interesting, for here was an irregular typhoid case, and that it was a mixture of the two diseases I do not believe, but lean toward the former diagnosis, for we do have irregularities during the course of a disease, and rarely have the two existing at one and the same time. Now this case is interesting because it happened at the time of a typhus epidemic, and secondly, having symptoms of both diseases.

Tympanites is frequent in typhoid, and while some say it is absent in typhus this is not the fact, for I, in my limited experience, have seen two cases, one of which died.

The eye in typhus is peculiar of itself. It has to be seen to be appreciated, and a typical typhus-fever eye is not soon forgotten. The pupils are contracted, sometimes finely so. The conjunctivæ are injected peculiarly, the little vessels radiate from the iris toward the periphery like lines from a light, with smaller vessels forming a net-work between the larger radiating vessels. The surface of the conjunctiva is moist. The eyelids are thin, and the cartilages are prominent, the edges red and dry, giving to the countenance a peculiar cast and spoken of as the "typhus eye," in contradistinction to the smooth, shiny, white "china eye" of typhoid.

Now in measles the eye is injected and the surface moist, accumulations of secretions forming and frequently running over lids. The lids are red, swollen, and moist, just the opposite of the "typhus eye."

I exhibit this relic of a very interesting case, and hope that future diagnosticians will not be so hasty in making diagnoses, but use the safest two methods, that of isolation and observation; and with our surgical friend exclusion I know all will be helped on the road to success with greater speed.

79 West 104th Street.

MORNING DIARRHŒA.

By L. W. ZWISOHN, M.D.,

NEW YORK.

I have read with great interest the article of Dr. F. Delafield, in the Medical Record, May 11th, entitled "Morning Diarrhœa," and I would venture to suggest the etiology of the disease of which the author says he has not been able to determine satisfactorily. As there can be no better experience for a physician than to study a disease in his own person, I will cite my experience, for I have been suffering from morning diarrhœa for years.

Dr. Delafield describes five varieties, all of which I have observed in my case, of course at different periods. At the beginning I had the first variety, the simplest; after a few months the disease progressed and took the form of the second variety, *i.e.*, the colicky pains, the exhaustion after the passage, the mental and nervous disturbances, the apprehension, etc. Then there appeared the fourth variety, *i.e.*, there was a sort of relation between the stomach and the colon, so that whenever I took food into the stomach there was a movement from the bowels. Then the disease took the form of the fifth variety, marked by the presence of considerable mucus in the discharge. This state of affairs kept up for years, passing alternately from the simplest form to the severest, and *vice versa*.

From my own experience I believe, 1. The chief cause is indigestion, aggravated by cold, anxiety, etc. 2. The main treatment is dietetic. Of course the progress is very slow, and some patients will think they get worse, and will never follow the directions of the physician. My patients, when I put them on a milk diet, after a week or two frequently say that they are not well yet, or they are getting worse. Some, or the majority of patients, as soon as they are better, will return to their old habits and suffer a relapse, and that is the reason why they get worse. I was obliged to keep up strict diet for a year before I was cured, and even at the present day I am careful with my diet. 3. I am of the opinion that the five varieties described by Dr. Delafield are all only degrees of the same affection, which begins with the simplest form and gradually comes to the severest.

A CASE OF PNEUMONIA SUCCESSFULLY TREATED BY COLD APPLICATIONS, GUAIACOL, AND STRYCHNINE.

By J. C. WORTHINGTON, M.D.,

MAJOR AND SURGEON, U. S. ARMY, FORT THOMAS, NEWPORT, KY.

Private F——, Company G, 6th Infantry, aged twenty-three, of temperate habits, was admitted to hospital, December 29, 1894, at 5.15 P.M., with a temperature of 103° F.; respiration, 36; pulse, 120. He had had pain in the left infra-mammary region all day. On auscultation at the time of admission, normal vesicular breathing was found at the seat of the pain and over the base of the lung posteriorly. Incipient lobar pneumonia was suspected. He was given Dover's powder, gm. 1, and four dry cups were applied to the painful side. Strychnine sulphate, gm. 0.002, was given at once.

December 30th, 7 A.M.—Temperature, 104 6° F.; respiration, 36; pulse, 116. Drowsy. It was ordered to continue the strychnine sulphate gm. 0.002, t. i. d., and to give tincture of digitalis t. i. d., and warm milk and beef-tea as nourishment. There was dulness and absence of respiratory sounds over the whole lower lobe of the left lung. Ordered cotton wadding and oiled-silk jacket to cover the whole chest. 12 M.: Temperature, 104° F. 7 P.M.: Temperature, 104.2° F.; respiration, 28; pulse, 116. Drowsy. No pain. Ordered strychnine sulphate gm. 0.001, hypodermically, at once, and at midnight. Also whiskey, 15 c.c., in milk, every two hours. Apply to side a flat rubber ice-bag filled with hydrant water (temperature, 54° F.), so as to cover the affected lobe of the left lung, this to be refilled every half hour during the night, but to be kept up only if grateful to the patient. The patient found this application comfortable and preferred to have it, and it was kept up regularly all night and until 10 A.M. on the 31st. It did not reduce his temperature.

December 31st, 7 A.M.—Temperature, 104.2° F.; respiration, 36; pulse, 116. Patient drowsy, but not delirious. Fine crepitant râles can be heard at the upper part of the lower lobe. Dulness over the whole lower lobe is marked. The patient still expresses himself as feeling a sense of comfort whenever the ice-bag is refilled with cold water. 9 A.M.: Temperature, 104.4° F.; respiration, 28; pulse, 112. As the temperature had now been over 104° F. for more than twenty-four hours and showed a tendency to rise, and having ordinarily seen cases of pneumonia prove fatal where such a high temperature persisted in the early stages, I determined to try the effect of the external application of guaiacol as a means of reducing the temperature. I accordingly applied, with a camel's-

hair brush, at 9.52 A.M., 2 c.c. of guaiacol to the inner side of the left thigh, from the groin half way to the knee, applying a brushful and briskly rubbing it in, and then another brushful until the 2 c.c. were absorbed; this required just eight minutes. The skin on which the guaiacol was applied was then covered with cotton batting and paraffined paper and a light bandage. The patient was well covered and it was directed that the cold-water bag on the side should not be refilled again. In fifteen minutes the patient began to perspire, the perspiration soon became very profuse. At 11 A.M. the temperature was 101.6° F.; respiration, 28; pulse, 112, but not weakened. The profuse perspiration continued. At 12 M. the temperature was 100.6° F. Strychnine sulphate, gm. 0.001, was then given hypodermically. Shortly after this the perspiration was checked. I believe that this was an effect of the strychnine, and that it was beneficial in preventing a too great fall of temperature. At 1 P.M. the temperature was 100° F. The patient was no longer drowsy, said his head felt clearer, and seemed altogether better. There was no indication in the pulse or voice that the profuse perspiration or rapid fall of the temperature had weakened the patient. It seemed, however, to produce a marked pallor of the face that was apparent for several days, as well as considerable emaciation. At 3 P.M. the temperature was 102° F.; at 5 P.M., 102.4° F. No alarming symptoms accompanied this reaction, and at 7 P.M. the temperature was 101.6° F., and at midnight 99.4° F.

January 1st.—Patient feels well. 7 A.M.: Temperature, 99.4° F. 10 A.M.: Vesicular sounds are returning in diseased lobe; respiration, 22. No cough or expectoration. There was none of either after the guaiacol was used. 12 M.: Temperature, 99.2° F.; 7 P.M.: Temperature, 100° F. After this convalescence was uneventful, and the temperature remained normal throughout.

The cold application to the chest in this case appeared to have no bad effect. If it did no good it made the patient more comfortable. The local application of guaiacol produced a crisis on the third day such as we might expect a few days later in a favorable case, but this was not the sort of case that I should have expected to terminate in that way. A steady rise in temperature and death during the night of the 31st, would have been the most natural prognosis to be given from the history of the case up to 9 A.M. on the 31st.

The use of the strychnine, gm. 0.001 every six hours, hypodermically, I consider to have played an important part in this case and to have prevented any undue depressing effect or subnormal temperature from the guaiacol. The whiskey, 15 c.c. every two hours day and night, may have contributed to the same result.

The man made a favorable recovery under tonics and a liberal diet, and was returned to duty with, to all appearances, a perfectly sound pair of lungs on February 3, 1895.

A CASE OF OPIUM AND CHLORAL POISONING.

By FRANK EDMONDS COUDERT, M.D.,

WALLINGFORD, CONN.

The following case may be of interest to the profession on account of the dual combination—chloral and opium.

On March 18, 1895, R. R—— consulted me at my office for some nervous trouble complicated with insomnia, for which I prescribed chloral in ten-grain doses, to be repeated in two hours if necessary. A few days later he returned complaining bitterly about his insomnia. This time I gave him a four-ounce mixture containing two grains morphia acetate and two and a half drachms of chloral hydrate, two teaspoonfuls at a dose, representing one-eighth grain of morphia and ten grains of chloral.

The following information was obtained from Mrs. R——: During the forenoon R—— was in an unusually happy state, and his wife, thinking it safe, left him shortly after the mid-day meal to take a much-needed walk. Three hours later she returned to find her husband lying on the floor in a state of profound coma. She hurriedly summoned assistance, and a neighboring physician was called in, who administered potassium permanganate in full doses, some eight or ten grains being given with one-fortieth grain strychnia, hypodermatically. I saw the patient shortly after and he was reacting well, complaining of being somewhat chilly, due, no doubt, to the chloral. He now confessed to having taken the whole contents of the chloral mixture. The following day my patient had quite recovered from the toxic dose. The question that now arises in my mind is whether the permanganate has antidotal effect upon the chloral as well as the morphine? When first seen he was breathing about five times to the minute and was extremely cold. Soon after the permanganate was given reaction commenced, and inside of three hours all symptoms of chloral and opium poisoning had vanished.

RATIONAL TREATMENT OF ERYSIPELAS.

By CARL ENGEL, M.D.,

MINDEN, IA.

The treatment of erysipelas has been undoubtedly disappointing to the majority of medical practitioners. The different methods described by different authors have been faithfully tried in their turn without producing the desired end. Nitrate of silver, iodine, and the drug treatment with oxide of zinc or starch-powder, covered with cotton, served only to increase the patient's sufferings. Many a physician has believed that he has found a specific, when in his very next case the same remedy will fail utterly.

In the last few years I have treated quite a number of erysipelas cases, and believed at one time I had in corrosive sublimate an unfailing remedy, but it will not do in every case.

On Wednesday, March 13, 1895, I was called to see Mr. John H——, barber by occupation, and intemperate in habits. Being a bachelor, food was of minor importance to him, his mainstay being whiskey. I ordered his face painted with a solution of four and a half grains of corrosive sublimate in an ounce of glycerine, and had this covered by cold, wet, 1 to 1,000 corrosive sublimate gauze. In addition I applied a rubber bandage around the head just above his eyes, waited a few minutes, and, after removing the tourniquet, pasted adhesive plaster, one-quarter of an inch wide, in its place. I have yet to see the case where the inflammation will overrun this line. The same procedure I employed at the temples. I gave no iron, in order to test whether the tincture of iron is "the remedy" in erysipelas or not.

Vesicles of double-pinhead size, containing yellowish serum, appeared on the face April 14th. There was the genuine pig-eye appearance, but the eyelids were not closed yet. Two sulphonal tablets of five grains each left for the night. The wet-pack was kept on continually. The patient's condition remained about the same up to the 16th, when the cheeks looked dusky, and the nose more natural. On March 17th I changed to carbolic-acid solution, 1 to 20, and plugged his ears with cotton soaked in carbolic oil, 1 to 40. On March 19th he was much improved; swelling of face down, ears better. Painted face with 1 to 40 carbolized oil. On March 23d patient was bright. Several abscesses developed, which I lanced, and introduced iodoform gauze strips.

Sulphonal and chloralamid were employed for the night, beside the following :

R. Acetanilide .....gr. xx.
Quinine .....gr. iv.
M. ft. pulv. Chart. iv. Sig. : One powder every three hours.

Thirty grains of chloralamid in four capsules were given at one time, March 19th, P.M. This dose kept the patient drowsy for several days, and though rest was desirable, its action was so prolonged that I would not repeat this dose in another case. The patient had the very worst of nursing during the first days, until his sister arrived from a distance. Now, as far as iron is concerned, I think we can safely dispense with it. The cold wet compresses were very grateful to the patient.

HYDRAMNIOS AND SPINA BIFIDA.

By A. N. WITHAM, M.D.,

SOUTH PARIS, ME.

I WAS called October 3, 1894, to attend Mrs. M—— in her fifth labor. I found an enormous abdomen—the largest that I had ever seen in a pregnant woman of her size. All the wise old ladies said, "Twins," as she had given birth to twins eight years before. Abdominal palpation failed to show part of the child. Vaginal examination showed a large bag of water protruding from a well-dilated cervix, but no part of the child was presenting. Pains were regular and strong, but labor did not advance. I became satisfied that it was a case of hydramnios, and told the lady her condition. I then ruptured the membranes, and the water gushed out like a brook, and ran off the rubber sheet over the edge of the bed into a vessel, and continued till I had caught nearly five vessels full. This, with what had run on the floor and had soaked into her clothes and the sheets, was certainly five gallons, or nearly forty pounds weight of fluid. I then found the feet presenting, gave ether, and delivered the woman readily.

The child was stillborn. It had no occipital bone, and the brain and spinal cord were exposed down to the last dorsal vertebra. The posterior convolutions of the brain and the fourth ventricle were plainly distinguished. The lower vertebræ were normal. The sac that had held the spinal fluid was ruptured and there was no tumor. The head was greatly extended, which made some deformity in this respect, but otherwise it was a perfect child.

A LARGE DOSE OF DIGITALIS.

By GEORGE F. KOEHLER, M.D.,

PORTLAND, ORE.

BEING called to attend a case of confinement at Sunny Side I had pre-arranged a small table near the bed of the patient, upon which I had placed bottles containing fluid extract of ergot, persulphate of iron, tincture of digitalis, and several other drugs which might be required in an emergency, as is my usual custom. After the birth of the child the placenta remained adherent. Waiting a reasonable length of time, I inserted my hand into the uterus. While detaching the placenta a great amount of hemorrhage ensued. Not wishing to remove my hand, I requested the husband of the woman (the only assistance at my command) to give the patient a teaspoonful of the dark medicine labelled ergot, and he promptly administered the remedy. Still retaining hold of the uterus, and after getting it well cleaned out, I ordered the husband to repeat the dose, which he did. The uterus now well contracted, I left the patient to wash my hands, when, to my surprise and annoyance, I discovered that my digitalis bottle was almost empty, while the bottle containing the ergot remained full. Sure enough my worthy assistant had given the patient two heaping teaspoonfuls of tincture of digitalis. I now gave the patient a teaspoonful of the fluid extract of ergot, and awaited with some anxiety the effect of the digitalis. In one hour the temperature rose to 102° F.; pulse, strong and full, 106 pulsations per minute ; the face flushed ; patient complaining of feeling warm ; otherwise comfortable.

Two hours after the last dose of the digitalis, patient resting easy. Temperature, 101° F.; pulse, 100. Afterpains well marked. 1 A.M., four hours later, patient perspiring freely. Temperature, 99° F.; pulse, 108 and weaker. Opium, carbonate of ammonia, and whisky administered. At 2 A.M., temperature normal ; pulse, 100 and stronger. Patient comfortable. At 7 A.M., temperature normal ; pulse, 88.

From this time on patient remained comfortable with the exception of severe after-pains, which lasted almost continuously for forty-eight hours, interrupted by the administration of opium. From the fact that about three fluid drachms of tincture of digitalis was taken and retained (no emetic being used), the moderate amount of systemic disturbance, the severity of the after-pains, and the apparent antagonistic action of the ergot, tend to make the case one of clinical interest.

FAILURE OF THYROID EXTRACT IN A CASE OF MYXŒDEMA.

By H. T. MILLER, M.D.,

SPRINGFIELD, O.

THE case of myxœdema reported by Dr. Abrahams in the MEDICAL RECORD of April 6, 1895, has prompted me to report the following interesting case. It dates back to June, 1892. Just previous to this date he had an acute attack of muscular rheumatism, and it was while treating him for this that my attention was drawn to an insulated dropsical condition in both supra-clavicular spaces that did not obey the physical law of gravity, did not pit on pressure, and would suddenly appear and disappear, without the least fluctuation in the quantity of urine secreted.

Physical examination revealed only a slightly hypertrophied heart ; pulse full and strong, and averaging sixty-five beats to the minute ; urine secreted was high colored, of low specific gravity, 1008 to 1010 ; acid in reaction ; non-albuminous ; no sugar ; small in quantity ; twenty-four to thirty ounces in twenty-four hours, and contained a diminished quantity of urea. The specific gravity at present has changed to 1030 and the color is normal ; this is likely to change suddenly, but the quantity remains always the same.

I will frankly confess that I was at a loss for a diagnosis, until the club-shaped nose, thickened lips and porcelain-like appearance of the face led me to believe that here was a case of myxœdema. The subjoined history of the case will, I believe, bear me out in my conclusions.

Mr. P——, aged seventy-one ; weight formerly 170 now 140 pounds ; height, 5 feet 3½ inches ; nativity, England, but has lived in this country for the past forty years. His own and family history is excellent. Occupation, that of an expert machinist. I would here interject that he used daily, for years, cyanide of potassium in his work. Whether this had anything to do with his present condition, I am not prepared to say, yet the following interesting fact, that no article of food, such as butter, meats, bread, milk, etc., can be left in his room for a length of time without assuming a decidedly greenish tint, should be noted in detailing this history.

Memory is defective, he will forget one moment what he intended doing the moment before, he is fretful, and at times becomes maniacal, with suicidal tendencies. The latter condition is preceded by a de-

termination of blood to the head, as manifested by the livid appearance of the face; the appearance of pallor is always followed by a subsidence of the paroxysm. At times there is an incoherency of speech, and when talking on a particular subject he is apt to go off at a tangent on some other subject. The nose is club-shaped; the lips are thickened; the eyes are expressionless; the face is puffed and porcelain-like in appearance, and the whole countenance marked for its stupid appearance—cretinoid. The tongue is hypertrophied and mapped; breath exceedingly offensive; the hair is shaggy and is falling off.

As stated before there are insulated collections of fluid over clavicles in supra-clavicular spaces, that do not pit on pressure and feel like cushions of air. There is a noticeable depression where the thyroid formerly was. Insulated collections of fluid have been observed on the chest. The hands are puffed and are closed with difficulty; the tips of the fingers are like cushions of air; there is dyspnœa; the body is nearly always cold, this is not only seemingly but actually so, as shown by the temperature varying from 96½° to 98° F., yet a peculiar feature noted is an occasional coldness of the knees with the legs and rest of the body warm. An herpetic eruption is at times noticeably prominent. The bowels are generally constipated, and the stools hard and clay colored; there is a slight œdema of the feet, which pit slightly on pressure. The odor of the room which he occupies resembles that of decaying animal matter.

Little good was accomplished by the use of diaphoretics and diuretics, in fact nothing seemed to avail. Thyroid extract never caused any improvement in the case. For over four months he has not taken any medicine at all, and I cannot see that he is in any way worse, excepting, perhaps, that he has grown weaker, yet he is able to be out of bed and to walk from room to room. I have little confidence that a change for the better will take place, as his age is against him. The failure of the thyroid extract in this case would not preclude my using it in another should it present itself.

A WELL-MARKED CASE OF KAHLBAUM'S SO-CALLED KATATONIA.

By L. W. DODSON, M.D.,

ASSISTANT PHYSICIAN TO THE BINGHAMTON STATE HOSPITAL.

F. G. D——, United States, male, aged twenty-seven, single, laborer; family history good; alleged causes, insolation and masturbation. Second admission. Was first admitted in January, 1894, remained three months, and was then discharged unimproved. During that time was depressed, had delusions of persecution, but showed little if any agitation when discussing his troubles. After discharge gradually grew worse, refused to talk to parents, laughed inanely when accosted, broke windows, destroyed furniture, and would only eat when food was placed in his room at night. Remained home five months, and was readmitted to the State Hospital, October, 1894. Was transferred to the infirmary ward in November, being confined in bed with the following symptoms: Limbs rigid and immobile, hands clenched, jaws fixed, rhythmical movements of oral, brow, and cheek muscles, causing continual grimacing and frowning. Muscles of extremities in a state of tonic contraction, with marked resistance to passive motion. When an attempt was made to move the arm or leg on one side, the corresponding limb on the opposite side moved in unison with it. When the limbs were released they immediately sprang back to their original position, not remaining wherever placed, as in catalepsy. Sensibility to tactile and painful impressions diminished. Titillation of soles of feet elicited no movement; pin pricks on arms and legs gave no response, but on soles of feet were responded to by a slight grimace after an interval of about three seconds. Tendon reflexes absent. Laid in bed with thighs abducted and widely separated, the legs flexed on thighs with soles of feet together, the head extended, the hands tightly gripping the scrotum. At times would suddenly straighten the legs, arch the back, and support the entire body weight on occiput and heels, remaining in the position of opisthotonos for from fifteen to twenty minutes. Usually preserves an unbroken silence, but at night frequently shrieks, and at times monotonously repeats the same profane words over and over. Refuses food when the attendants are near, but has bulimia, and when not watched will not only bolt his own meal, but suddenly jump from bed and gormandize that of the other patients. Passes his urine and fæces in bed. All the symptoms are intensified when he is under observation. Under treatment his condition ameliorated somewhat, but he has relapsed, and now presents almost all of the above-mentioned features.

This case appears to fill all the requirements for the diagnosis of katatonia. The insidious onset with melancholy and unsystematized persecutory delusions, the marked resistance to passive motion (symptom of negativism), the sudden spasmodic contraction of the extensor muscles with opisthotonos, the athethoid movements of the facial muscle, the obstinate silence alternating with the monotonous verbigeration of profane words, the sudden shriek, due probably to hallucination, the bulimia, the state of pseudo-pathos rather than true pathos, the melancholy being more apparent than real, and the hysterical element in that all symptoms are intensified when he is under observation, present in toto, a symptom-complex characteristic of no other disease.

There is another case in the hospital at present simulating katatonia, yet clearly distinct. It is that of a young female, aged twenty-three, with stuporous melancholia and catalepsy. There is no resistance to passive motion, no sudden spasm of the muscles; they remain in whatever position placed. No verbigeration. She refuses all food, and the mental condition is one of acutely intense melancholy.

Certainly, the symptoms in these two cases can be clearly differentiated. Etiologically and pathologically, it is impossible to draw a sharp line between the so-called katatonia and stuporous melancholia with cataleptoid symptoms. Clinically, however, the difference would be obvious to the most casual observer, and all honor is due Kahlbaum and Kiernan for having clearly and concisely marked out the characteristic features of katatonia.

ESSENTIAL DROPSY.

By MARCELL HARTWIG, M.D.,

BUFFALO, N. Y.

In my first communication about this subject, in the MEDICAL RECORD of September 27, 1890, I had already ventured the hypothesis of bacterial origin. A

Surgical Suggestions.

Perforating Ulcer of Stomach.—Many surgeons are disposed to attach more importance to the toilet of the peritoneum than to the actual searching out and sewing up of the point of perforation.

Symphyseotomy is indicated in flat pelves with a conjugate of from 67 to 88 mm.; in funnel-shaped pelves with a transverse diameter of pelvic outlet of 88 mm., or less; in cases of dystocia caused by tumors of the pelvic cavity; in cases of abnormal size of the fœtus, but with normal pelvis. It is easily performed.—Winterberg.

Ganglion.—Inject five to ten drops of tincture of iodine and bandage.—Duplay.

Use Black Pins in surgical dressings, since they will not rust and can be more readily seen.—Medical Age.

Iliac Abscess.—The indications for operation are: 1. Where the abscess is large and making pressure upon important organs; 2. Where the abscess is increasing rapidly in size; 3. Where there is danger of rupture of the abscess into the peritoneal cavity.—Young.

Iliac Abscess may not be of spinal origin, but arise from hip disease, perforating the acetabulum, innominate disease, etc. Sarcoma also occurs in this region.—Willard.

Appendicitis.—1. The first inference from a general consideration of ileo-cæcal troubles is that all collections of pus should be evacuated by free incision followed by gauze drainage. 2. Should the appendix be involved in the abscess and already in a necrosed state, it is fair to infer that the canal is closed so that there is no communication with the cæcum, and hence excision is not requisite. 3. If, on the contrary, the appendix is found to be enlarged and indurated without perforation, it should be ligated and removed at once. 4. In suspected cases of appendicitis, without the signs of suppuration or the presence of a local swelling or induration, an exploratory operation by a transverse incision above Poupart's ligament, with separation of the muscular fibres, should be resorted to without delay. 5. With a clear diagnosis of appendicitis, a longitudinal incision on the outer border of the right rectus muscle, extending downward over the cæcum, is best adapted to reach the appendix. 6. In all cases of recent occurrence, in which suppuration has not appeared, but there exists an inflammatory process of the appendix, it should be removed.—Gaston.

Empyema.—The indiscriminate use of antiseptic injections cannot be too strongly condemned, since many fatal results have immediately followed its practice. Immediate washing out of the pleural cavity after operation, for ordinary empyema, is always an inadvisable and hazardous procedure, and is only permissible at later periods when practised with the greatest caution.—White.

Fistula in Ano.—After the sphincter is thoroughly stretched, the rectum is washed out carefully with bichloride solution 1 to 4,000; the fistula is split open. Then the indurated tissue is thoroughly removed, taking care to cut out clean both ends of the fistula, not leaving any unhealthy skin or mucous membrane at these points. Search for branch channels, treat them in the same way, and finally close the wound with catgut, using only a single row of sutures.—Cook.

Chancroid beneath the Prepuce.—Wash out with boric solution, inject beneath the foreskin a saturated solution of chloride of zinc, after about a minute wash again with boric acid and perform immediate circumcision.—Cordier.

Watch the Respiration in chloroform anæsthesia. If this keeps good, the heart is not apt to give trouble.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 22, 1895.

Egbert H. Grandin, M.D., President, in the Chair.

Refracting Opticians.—In accord with a resolution offerred by Dr. Van Fleet at the last meeting of the Society, Mr. Taylor, counsel for the Society, sent a written opinion to the effect that opticians, like other manufacturers and dealers in instruments, were permitted by the statute regulating the practice of medicine to fit instruments, such as trusses and glasses, for those in need of them. Mr. Taylor doubted, therefore, whether the optician who advertised to fit glasses could be held for violation of the law.

Dr. Van Fleet thought there could be no doubt but what advertising opticians violated the spirit of the law, whether they violated the letter or not. At least one of them had an advertisement in the County Directory, which he thought amounted practically to an endorsement of his work by the County Medical Society. That advertisement, he said, ought to be expunged, and he offered a resolution to that effect.

Drs. S. D. Powell and Daniel Lewis doubted whether the advertisement in question led physicians and other persons astray to the extent implied in Dr. Van Fleet's remarks. At any rate, since it seemed to be within the law, and a written agreement had been entered into with the advertiser, to cancel it without his consent would render the Society liable to an action at law.

Dr. Van Fleet still strenuously opposed such misleading advertisements, but withdrew his original motion and moved that the comitia minora be instructed to consider the best method of having this particular advertisement taken from the Directory. Carried.

The Status of the Physician when Called to Cases of Abortion.—The following are extracts from a communication from the counsel of the Society, Mr. Robert C. Taylor:

The Medical Society of the County of New York has requested me, as their counsel, to advise them what is the status of a physician who has been called in to attend a case where a miscarriage or abortion has been brought about, in order that the rights of a professional man in such a delicate predicament may be more distinctly understood and he may be able to render the offices of humanity freely, without fear of himself being suspected as accessory to a crime.

It may be said, by way of preface, that there is no definite or positive rule by which a physician may be guided in such a case; and the question, therefore,

becomes one rather of general good sense and prudence. It is assumed that the physician is brought face to face with a state of facts in which he has reason to fear that a criminal operation has been performed, and yet cannot positively so conclude.

At common law there was a certain crime known as misprision, but in New York State the common law has been superseded by the penal code, and misprision [failure to report a suspected crime] as such is not a crime here.

There are many laws requiring reports to boards of health of contagious diseases, deaths, etc. As to the duty of reporting matters to the coroner, we find no statute of general application throughout the State, but note the following sections of the consolidation act affecting New York City. Section 1773 [on the cases of death which shall be reported to the coroner]. Section 1775. It shall be the duty of any citizen who may become aware of the death of a person who shall have died in the manner stated, to report such death forthwith to one of the coroners, or to any police officer, and such officer shall, without delay, notify the coroner of such death, and any person who shall wilfully neglect or refuse to report such death to the coroner shall, upon conviction, be adjudged guilty of a misdemeanor, and shall be punished by imprisonment in the county prison not exceeding one year, or by a fine not exceeding five hundred dollars, or by both such fine and imprisonment.

It would thus seem that by the very wording of the statute there could be no crime in the mere failure to report any suspicious case which did not result in death.

It therefore follows that the physician's duty to report a case of illness which he suspects to involve criminal malpractice, is not a duty imposed upon him by any statute ; and that for his failure so to report, he is not liable to any specific punishment.

The practical aspect of the case is, that if the circumstances are such as to lead one to believe that malpractice has been committed, the physician runs the risk of suspicion as an accessory. His duty under the circumstances, then, relates only to himself ; and his conduct should be such as to conduce to his own protection. If he receives a call to attend an urgent case, he cannot decline it, even though it be suspicious. If the patient is in the house of a midwife, or where there is the slightest reason to believe that a criminal act has been committed, or that death might ensue, he should call in a consultant who could prove the integrity and wisdom of the treatment. His suspicions should be communicated to the coroner, thus casting upon that official the duty of ferreting out the crime. In all that he does he should be open and above board, so that suspicion, if any arise, may be disarmed. This is, after all, all the advice that can be given.

If it be suggested that the physician is, by law, incompetent to divulge information professionally acquired, a sufficient answer is found in the statute creating the incapacity : A person, duly authorized to practise physic or surgery, shall not be allowed to disclose any information which he acquired in attending a patient, in a professional capacity, and which was necessary to enable him to act in that capacity.—Code Civ. Proc., Sect. 834.

A most embarrassing mass of adjudication has been the result of the effort to construe this enactment ; and its true meaning is much in doubt. His clear duty to protect himself by making the disclosure would not, therefore, be complicated by any supposed duty of silence existing toward the patient. As far as the risk of being held liable for slanderous or libellous statements is concerned, it is enough to say that a physician who, in good faith, had reason to believe that the crime of procuring an abortion had been committed, would be protected from any action for damages, if he communicated his suspicions to the proper authorities, even if it afterward turned out that the person as to whom he had given the information was not guilty of the suspected crime. If the physician idly disseminated his suspicions, and they turned out to be false, he would then plainly and justly be liable to the individual whom he had carelessly slandered.

Nevertheless, if, after all precautions, a physician should be arrested upon suspicion of being accessory to an act of criminal malpractice, his remedy, if he is innocent, is to prosecute those who caused his arrest. As against the newspapers, if he was in fact arrested and they published annoying accounts of the matter, he would have no remedy ; but this is an unfortunate case for which it is impossible to provide.

Health Board gets Thanks.—Dr. S. D. Powell said he had noticed that the Board of Health had seen fit to instruct their inspectors as to their duties relating to medical practitioners and their patients. As this was in line with a resolution passed during his term of service as president of the Society, he moved that a vote of thanks be extended the Board of Health for the fair and just treatment which they had extended the practitioners of the city. Carried.

Apoplexy.—This was the scientific subject for discussion during the evening. Three papers were read.

Etiology and Pathology.—Dr. Edward D. Fisher read a paper on this division of the subject. Under cerebral apoplexy he considered cerebral hemorrhage, embolism, and thrombosis. The term apoplexy signified to strike down, and an essential symptom was loss of consciousness, and associated with it there was usually paralysis of one-half of the body, due to impairment or destruction of some part of the brain. The commonest cause was hemorrhage, and this was due to disease of the blood-vessels. There was a natural tendency to atheromatous changes in the vessels in advanced life. Alcohol and syphilis were also predisposing causes of arterial disease. Associated with the arterial sclerosis, there was usually sclerosis of the kidneys and concomitant hypertrophy of the left ventricle of the heart. Hemorrhage in early life was likely to occur in persons of sedentary habit, who ate excessively, the tendency to arterial sclerosis being much augmented if alcohol were used even in moderation. Chronic lead-poisoning would produce arterio-sclerosis and interstitial nephritis. Heredity might be a predisposing cause, especially in showing a tendency to arterial degeneration and kidney disease. The old idea that short-necked persons were especially liable to apoplexy had hardly any scientific support, except so far as increased adipose tissue was an indication of excessive eating.

Dr. Fisher thought syphilis was rarely the cause of cerebral hemorrhage, although it was a common cause of thrombosis. In many cases alcohol and syphilis were combined and had a deleterious influence on the kidneys. Hemorrhage might occur during acute infectious fevers, also in scurvy and purpura. Intra-uterine hemorrhage into the brain might take place as a result of operation or tedious delivery, but later, when the cases came to autopsy, it was very difficult to state what was the original cause of the brain sclerosis. In cases seen by him it probably had been occlusion of some vessel. The cerebral hemorrhage might be induced immediately by some strong emotion, as public speaking, bad news, or taking a cold bath, which drove the blood into the diseased vessels.

The next most frequent cause of apoplexy was thrombosis of the cerebral vessels. It occurred oftenest in early life—twenty-five to forty—and was usually due to syphilis, but might be due to alcohol, etc. Dr. Fisher believed that thrombosis occurred oftener in old people than was generally supposed. Sudden and complete recovery from attacks of apoplexy in the aged suggested incomplete thrombosis. There might be little evidence of disease at autopsy. There was probably interference with the circulation, especially in the middle cerebral. He believed, also, that œdema or cere-

bral effusion was sometimes a cause, notwithstanding Watson's old theory of serous apoplexy had been largely discarded. The local serous effusion was apt to disappear on cutting into the dura, and be overlooked.

The next most frequent cause of apoplexy was embolism, which usually was due to a clot starting from the heart, and which was more apt to proceed to the left half of the brain than to the right, and to involve the middle cerebral and its branches. Brief allusion was also made to meningeal lesions resulting in symptoms like in apoplexy — unconsciousness and hemiplegia. So-called birth palsy was often due to meningeal hemorrhage. Pachymeningitis and an alcoholic history were frequently combined in the paralysis of the insane.

The pathological changes were due, first of all, to disease of the blood-vessels. The hemorrhage was usually from the smaller vessels. The larger vessels being rigid, from changes in their walls, allowed the blood to pass with unrestricted force into the smaller ones whose weakened walls gave way. The blood-clot changed in appearance with time. A cyst might form, its contents might become absorbed and leave scar-like tissue. In plugging of the vessels there was anæmia, later softening. According to the vascularity of the parts there was gray or white softening. The changes seen would vary according to the remoteness of the autopsy from the time of the stroke. In old cases there were structural changes in the nervous areas and corresponding tracts proceeding to the cord. As early as two weeks descending degeneration was found in animals, somewhat later in man. The lateral sclerosis left by such degenerated tracts was on the same side as the hemiplegia in the cord, on the opposite side above the crossing of the tracts in the medulla. The most common site of the hemorrhage or occlusion of vessels was in the internal capsule.

Symptomatology and Treatment.—Dr. William H. Draper said that since the term apoplexy was generally restricted to cases of intra-cranial hemorrhage, he would ask attention to the symptomatology of that condition. Although he knew perfectly well the difficulty of differentiating the unconsciousness or the apoplectic fit the result of hemorrhage from that which was the result of embolism or thrombosis, yet he thought the differential diagnosis could usually be made. In describing the symptoms of apoplexy he spoke of those which were primary and those which were secondary. The primary symptoms were those belonging to the attack, the secondary those associated with the lesion. The primary were divided into those preceding and those accompanying the attack. The symptoms which preceded it consisted of disturbed sensation, as pain in the head, nausea, paræsthesiæ of the extremities, which could hardly be regarded as premonitory of the attack, as they were often absent, and were often present in derangements of the cerebral circulation and disease of the peripheral nerves. Severe pain in the head had preceded the attack in a few of his cases, but usually this symptom pointed to intra-cranial syphilis unless present only a few hours before the hemorrhage.

The symptoms of the onset varied. There might be sudden agonizing pain in the head while the victim was at his work or in the enjoyment of perfect health. He might cry out, and exclaim that he was giddy and could not see, or that he had no feeling in the limbs, and within a few minutes become unconscious, with or without convulsions. Instead of this sudden attack, the patient might be taken with a sense of general exhaustion, perhaps nausea and vomiting, and then inability to use one leg or arm. Indeed, the attack might be of varying degrees of suddenness, depending upon the location and extent of the hemorrhage. If the patient were attacked in his sleep, he would awake to find himself paralyzed on one side. Whether in such cases the attack had been preceded by convulsion or coma was usually impossible to determine.

When called to cases of apoplexy we observe considerable variation in the degree of unconsciousness. It might be complete, with absolute loss of pain sense and relaxation of the muscles, even of the sphincters. There might be an effort to answer simple questions. The head might be turned away from the paralyzed side, the pupils might be equal or unequal, the reflexes more or less completely abolished, the surface might be bathed in perspiration, the lips cyanotic, the temperature might be below normal one, two or three degrees, but it might rise in twenty-four hours, and register in fatal cases toward the end 106° F. or more. In favorable cases it usually returned to normal in from one to three days. The pulse might be increased or diminished, and vary in force and rhythm. Dr. Draper gave a graphic picture of the respiratory difficulty in these cases, which might be due partly to the influence of the stroke on the respiratory centre, partly to mechanical obstruction. The unconsciousness might last forty-eight hours and be recovered from slowly, or it might disappear in a much shorter period. In his experience the longer the unconsciousness the more serious the prognosis.

In distinguishing cerebral hemorrhage from embolism and thrombosis, the former was characterized more by suddenness. The previous history, the condition of the heart, and the age of the patient were further aids in differentiation. The secondary symptoms of apoplexy were omitted.

Treatment. — Regarding treatment, Dr. Draper thought there was probably no other condition in which the doctor felt himself so helpless as in cerebral hemorrhage. Something had to be done quickly, and Dr. Draper felt disposed to try bleeding. To relieve the breathing and prevent stertor, turn the patient on the side, or pull the jaw forward and thus prevent the tongue from falling back into the throat. The ice-bag, recumbent posture, purge, mustard foot-bath, all had reference to the circulation, being intended to drive the blood from the head.

Points in Differential Diagnosis.—Dr. Charles L. Dana read the last paper. He used the term apoplexy in the sense described by Dr. Fisher, including cerebral hemorrhage, embolism, and thrombosis. A person whom we found in a state of coma suggesting apoplexy might be suffering from one of a dozen or more conditions. The more probable ones were hemorrhage, thrombosis, embolism, hysteria, syncope, alcoholism, concussion of the brain with shock, poisons of various kinds, uræmia, sudden bursting of an abscess, epileptic attack. He would not undertake to point out all the differential points relating to these conditions. The more common of these states which we were called upon to differentiate from apoplexy were syncope, alcoholism, concussion and shock, epilepsy, and opium poisoning. Most of these could be readily excluded after the physician had learned the history and mode of onset of the attack, the condition of the pupils, urine, and heart.

In syncope there was loss of consciousness but no paralysis. In the condition which gave ambulance surgeons so much trouble, alcoholism with blow on the head, against apoplexy there was alcoholic breath, usually absence of hemiplegia and facial paralysis, no stertor to the breathing, the patient could almost invariably be aroused and muttered some incoherent words. In hysterical apoplexy the patient could be slightly aroused, there was no stertorous breathing, no facial paralysis, only hemiplegia affecting arm and leg; the hemianæsthesia often responded to pricking with the pin, there was no rigidity of the affected side, no exaggeration of reflexes, the pupils were equal.

In differentiating between cerebral hemorrhage, thrombosis, and embolism, one should remember, when in the presence of a case of apoplexy that, so far as chance was concerned, it was two to one in favor of hemorrhage, and if the patient were in the prime of

life, between forty and sixty, it was six to one in favor of hemorrhage. Suddenness of onset, profoundness of coma and of hemiplegia favored hemorrhage, next embolism. The extremes of adult life pointed to thrombosis. Where the attack came on gradually, with symptoms of headache, vertigo, and there had been slight hemiplegia a few days before which had disappeared, the probability was strongly in favor of thrombosis.

Stout people, or those with the so-called apoplectic temperament, were rarely subject to thrombosis. If the attack were sudden and cardiac disease existed, paralysis following loss of consciousness, there was probably embolism. In thrombosis there was often considerable paralysis before loss of consciousness. Anæsthesia and moderate hemiplegia pointed to thrombosis.

Regarding the temperature, which should be taken in both axillæ, in thrombosis and embolism there was hardly ever any disturbance of the temperature the first days, it being even on the two sides of the body, whereas in hemorrhage he had found the temperature a degree or a degree and a half higher on the hemiplegic side. In acute softening from embolism and thrombosis he had found the temperature rise about one degree perhaps one or two days after the attack, while in hemorrhage it rose to two or three degrees by this time, and began to fall the third day if the case got better, but continued to rise if it went on to get worse. The temperature, therefore, was of value in diagnosis and in prognosis. It had not received the attention which it deserved.

Syphilis and Apoplexy.—Dr. Joseph Collins laid stress on the sinister effects of syphilis in leading up to arterial degeneration and apoplexy, whether the apoplexy were due to thrombosis or to embolism. It was of extreme importance because of its frequency and the valuable indication which it furnished in treatment.

Dr. William H. McEnroe, speaking of the differential diagnosis between hemorrhage into the pons and opium poisoning, said that in the former the coma was more profound, in the latter the patient could be roused to an extent and would answer intelligently, as far as he answered at all. The pulse was full and healthy in the early stage of opium poisoning, while in hemorrhage it was wiry, sometimes slow, sometimes rapid, but never full, strong, and regular. In opium poisoning the whole body was bathed in perspiration, and the respirations were less frequent than in hemorrhage.

Dr. Van Santvoord spoke of drugs. They were used to check continuous hemorrhage. He had given aconite with the intention of weakening the heart-action and reducing the blood-pressure in the vessels. He thought nitrate of sodium being slower in its action than nitrite of amyl, would be safer. Atropia commended itself to him as the best remedy.

Physicians and the Presidency of the Board of Health.—Dr. Warner read some resolutions sent by Dr. H. D. Chapin, endorsing the bill before the Legislature giving the Mayor power to appoint either a layman or a physician president of the Board of Health. The present law made it obligatory upon him to appoint only a layman. The resolutions were adopted.

Similarity of Features in Trades.—Dr. Louis Robinson has shown to the world the interesting fact that new born babies can hang in mid-air from a stick. He now assures us that people who follow the same trade get to look alike. He does not say whether this applies to doctors.

Berlin Physicians are supplied with diphtheria antitoxin free of cost, on condition that they return accurate reports of the cases in which it has been used.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, May 20, 1895.

Samuel B. W. McLeod, M.D., President, in the Chair.

Deformity Caused by Adduction and Flexion in Hip-disease, with a Mechanical Demonstration Thereof.—Dr. A. B. Judson read a paper with this title (see page 13).

Dr. Lewis A. Sayre was requested to open the discussion. He thought the demonstration had been so clear as to leave nothing to discuss. It was a simple statement of facts with a clear demonstration. He was very glad to have heard the author impress the great importance of educating children with deformity from hip-disease to walk. If one would get them off of the lame limb by giving them a crutch and then teach them how to walk with proper rhythm, he would accomplish a great deal. Keep concussion away from the joint and the motion could be increased a great deal. Deformity resulted largely from muscular contraction, and this took place in order to protect the joint from concussion. Have the child walk with a crutch under the arm or perineum, make gentle traction, then instruct it to walk properly, and a large amount of good would be accomplished.

Tincture of Iodine in the Treatment of Chronic Suppurative Inflammations of the Ear.—Dr. F. P. Hoover read the paper. He had tried to stop the discharge from the ear in chronic suppuration by such agents as nitrate of silver, bichloride solution, boracic acid, iodoform, but with indifferent success, and at last had decided to test tincture of iodine. This was applied on a probe wrapped with cotton. If the perforation in the drum membrane was small, it was enlarged. The applications were made two or three times a week. The patient complained at first of a tingling sensation, but this soon passed off. When freely applied some of the medicine trickled down into the Eustachian tube and caused a taste of iodine. There had been no ill effects.

The curative results had been striking, as shown by the recital of several illustrative cases. Case I.—Age of patient twenty years, duration of suppurative discharge five years; no permanent results under various remedies until tincture of iodine was tried. After its use for three weeks the discharge ceased and had not returned. Case II.—Discharge for fourteen years, failure under nitrate of silver, etc.; recovery in three weeks after commencing tincture of iodine applications. In Case IV. the man was thirty years old, had had aural discharge for twenty years; was cured with tincture of iodine in eight weeks; saying he then felt like another man. The treatment was best carried out in private practice, since it required regular attendance.

Dr. N. J. Hepburn said he had used tincture of iodine in suppurative discharges from the ear at intervals for ten years, and had found it valuable in some of the obstinate cases with, as one might say, a pyogenic lining membrane. A young woman came to the clinic about 1884, with a history of suppurative discharge which had not ceased entirely at any time during twenty years. Since she said everything else had been tried and failed, he resorted to tincture of iodine, and the suppuration ceased entirely after the third application. It had not returned when he saw her about six months later. One advantage of tincture of iodine was the absence of pain attending its application. The burning sensation ceased as soon as air was shut off by putting cotton into the ear.

Dr. S. M. Payne had been using tincture of iodine since the summer of 1892. At first he used it very cautiously, but later, finding no injurious results, he saturated the cotton with it and then obtained much better results; all the patients recovered. By its free use some of the iodine ran down the Eustachian tube

and was tasted, and it was only after such free use that all the patients were cured of their chronic discharge. But where there were granulations this method of treatment had to be supplemented by curettage or application of trichloracetic acid. The treatment was also followed by marked improvement in hearing.

Dr. Quinlan said that about seventy-five or eighty per cent. of all cases of chronic inflammation of the middle ear, whether suppurative or catarrhal, depended upon rhino-pharyngeal irritation, and it seemed to him that the best way to get rid of the ear trouble was to remove the cause.

Dr. Hoover replied to Dr. Quinlan that in one of his cases there were enlarged tonsils and hypertrophy of the turbinate on the left side. These were cured, but the ear was still running at the end of five or six weeks, and ceased to do so only after the use of tincture of iodine.

Multiple Cerebro-spinal Sclerosis.—Dr. W. C. Gilday reported a case in which he had made the diagnosis of multiple cerebro-spinal sclerosis and stated that the diagnosis was confirmed by autopsy, sclerotic patches varying in size from the head of a pin to a bean being found on the cerebellum, pons, medulla, cord, and sciatic nerve. The symptoms had come on gradually, beginning about 1875, and resulting when Dr. Gilday first saw the patient (1893), three months before death, in complete paralysis of the entire body excepting the neck. The muscles were flabby but not atrophied. Passage of the fæces could not be restrained when the desire came. No analgesia, no loss of temperature sense, perception of odor diminished. Almost complete loss of vision. Marked nystagmus. The mind was not affected. Prior to these marked symptoms, the patient felt as if he would "topple" over on attempting to cross the room; there were some pain sensations, paralysis of the legs occurred some years before paralysis of the hands. There had been a history of a fall some time before the commencement of the symptoms. Death came suddenly.

Dr. Von Donhoff thought the clinical history of the case was not that of disseminated sclerosis. It impressed him rather as one of spinal irritation from severe shock, which finally ended in changes, perhaps undiscovered, which caused paralysis and death.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 16, 1895.

Joseph D. Bryant, M.D., President, in the Chair.

Donation to the Library.—Dr. George Thomas Jackson announced recent donations to the library, including the sum of $200, given by Mrs. Elizabeth A. Galloway, through D. Ellsworth Eliot; also a portrait of Professor Thiersch, drawn and presented by Dr. Arpad G. Gerster. A vote of thanks was extended the donors.

A Clinical and Bacteriological Study of the Gonococcus as Found in the Male Urethra and in the Vulvo-vaginal Tract of Children.—Dr. Henry Heiman read the paper, which was illustrated by lantern slides and cultures of gonococci on various media, as well as of other diplococci obtained from the genito-urinary tract. (See page 769, vol. 47, Medical Record.)

Dr. Sigmund Lustgarten said he appreciated the great task performed by Dr. Heiman, and the fact that it offered little room for criticism except it were founded on work of like positive character, yet he felt like making a few remarks on one point, namely, the diagnostic value of the gonococcus under the microscope. His own researches were published in 1887, in which he stated that there was a diplococcus found in the normal male urethra closely resembling the gonococcus, and which could not always be distinguished from this by the Gram test. He had since given attention to the same point, and had been compelled to retain the same opinion. Even a pupil of Neisser had admitted the possibility of a mistake in the differential diagnosis between the two in at least five per cent. of the cases. Of late the opinion had again been brought forward that the secretions from the male urethra might be contagious even if the gonococcus were not present. He must confess that personally he had often been very much embarrassed to decide this question, and he thought we must admit that at present there were a number of cases in which we could not give a positive opinion based on the microscope. Probably, like in diphtheria, we would have to fall back on cultures for assistance, and chest serum, which Dr. Heiman had so highly commended; could always be obtained as a culture medium. Microscopic examination, in spite of the much-praised method of Gram, was not alone reliable.

Dr. Ira Van Gieson was glad to be able to speak of Dr. Heiman's work in terms of highest commendation. It had been careful and painstaking, and little disposition had been shown to draw deductions which were not substantiated by facts. Few could realize the amount of work embodied in such a paper. Yet it was of enormous importance because of the danger of one affected with gleet and contemplating marriage infecting the wife and giving rise to serious uterine and tubal trouble. He thought we were ready to go back to Noeggerath's original dictum, that fully eighty per cent. of these troubles were due to the gonococcus.

Referring to the practical bearing of the work, he might say that in antiseptic therapeusis the discovery of the gonococcus had been of little value. The best treatment of the urethritis had been found empirically before the discovery of the gonococcus, and the meddling with antiseptics later had probably done more harm than good. But the value of the discovery of the gonococcus had been great in the management of the later stages of the disease, for it had led to a better knowledge of its pathology and thereby to a more rational management.

Dr. Van Gieson would say deliberately that a great deal of work in identifying the gonococcus in the later stages of gonorrhœa had been careless and unreliable, consisting simply in observing its shape and size on the cover-glass. If we would make the diagnosis purely on morphological ground in the stage of gleet, it should always be supplemented by Gram's method. The pseudo-gonococcus was frequently mistaken for the gonococcus. As to its persistence for months, and even years, after the primary urethritis, he thought we were not yet able to say, and the only way to settle the question was by work of just the character performed by Dr. Heiman.

As to the case referred to in the paper in which Dr. Van Gieson made the autopsy thirteen days after the acute gonorrhœal urethritis from inoculation, he would say that the urethral membrane simply looked red, perhaps redder than usual in the anterior portion, but in the deep or prostatic portion there was severe damage. It was crowded in the prostatic portion with small round cells beneath the epithelium. The epithelium was abraded in many places, there were extravasations of red blood-cells beneath the epithelium, and many of them had found their way to the free surface of the urethra.

It was to be remarked that the first urethritis was altogether different, both clinically and pathologically, from subsequent attacks, doing much less damage to the urethra. The first attack was something which one could recover from, as few changes were present, but after several attacks there were extensive changes, leading to connective tissue and contractions.

He could confirm the statement in the paper, that a discharge from the urethra might show no gonococci for days and weeks, yet after irritation, as by division of a

real or imaginary stricture, their presence would be detected. Examination on three successive days was not sufficient. In conclusion, he impressed the necessity for applying Gram's method, and of deciding the questions, if it were possible, how long the gonococcus was capable of persisting, and whether there was such a thing as so-called latent gonococcus.

Dr. Heiman, in some concluding remarks, described how he applied the Gram method.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL COUNCIL—PHARMACOPŒIA—IRISH CONJOINT BOARD—IMMUNITY AND SNAKE-POISON—SOCIETIES' CLOSING SESSION—THICKENED MESENTERY AS A TUMOR—PYLEPHLEBITIS—RENAL GROWTH—ROYAL SOCIETY.

London, June 14, 1895.

Besides the subjects I have already noticed the General Medical Council discussed before separating the coming Pharmacopœia and the alleged defects of the Irish Conjoint Board. As to the Pharmacopœia the committee thereupon had gathered information from medical authorities, the Pharmaceutical Society, from India, and the colonies. Drs. Brunton, Fraser, and Walter Smith had been requested to act as referees as to the properties of certain preparations, and help had also been called in on chemical and botanical matters. Professor Attfield's ninth report was received and ordered to be printed, and some conversation took place as to his remuneration. It was also said that a considerable sum would have to be paid to the Pharmaceutical Society for its assistance—a statement somewhat surprising to those who remember the anxiety once displayed by that Society to take a share in the work and the off-hand manner in which its kindly offer was rejected. It must be admitted that whatever may be the excellences of the volume it is likely to be excessively costly, and the preparation seems to be conducted in a clumsy manner. The College of Physicians used to give us a convenient Pharmacopœia in two sizes at a reasonable price. Now the Council lavishes on the work enormous sums, and not a few fail to find it of the value they anticipated. Committees are no doubt useful, but when they have to engage experts to do the work at much greater cost than would be expended in other cases on the same experts, it is no wonder people are asking what is the use of the committees? A vote of £3,000 was taken on account by the Pharmacopœia Committee, and Dr. Tirard was engaged to act as secretary.

With regard to the allegations against the Irish Conjoint Board and the Dublin Apothecaries' Hall there was an animated—not to say ill-tempered—discussion. Sir P. Smyly declared that the Dublin College of Physicians had boycotted the Hall, and defending the expression said there were three kinds of boycotting—shooting a man dead, shooting him in the legs, and preventing him from obtaining food. All three methods, Sir Philip declared, had been employed by the College of Physicians against the Conjoint Board. The jealousy of the College toward the Hall has no doubt been intense, though it may be admitted that there have been shortcomings. If the Hall could not get members of the Dublin College to act as examiners on account of this jealousy, what was to hinder members of the London or Edinburgh College being appointed? There are plenty of men who would be ready to take a trip across the Irish Channel and examine the candidates—men, too, in whom full confidence might be placed as to the just discharge of the duty. However, the Conjoint Board will cease to exist very soon, its term of agreement coming to an end. What the Privy Council is to say to an expiring Board we may yet see.

The subject of immunity attracts still further attention. On the 6th inst. Professor Fraser brought before the Edinburgh Royal Society the results of a research he had carried out on snake poison. From his investigations it would seem not unlikely that we are on the eve of discovering how to prevent, and possibly cure, the effects of a venomous snake-bite. Dr. Fraser has succeeded in rendering rabbits immune to from twenty to fifty times a lethal dose of snake-poison. His previous researches on strophanthus gives confidence in his care and exactitude, and great hopes are entertained as to the outcome of his work.

Our societies are closing their doors for the session. On Tuesday last the Medico-Chirurgical held its concluding meeting, when two papers were read—one on "The Development of Mammary Functions by the Skin of Lying-in Women," the other on "Intra-peritoneal Rupture of the Bladder."

At the concluding meeting for the session of the Clinical Society, Dr. F. Lucas Benham read a paper upon a "Case of Thickened and Contracted Mesentery simulating Tumor in a Case of Cirrhosis of the Liver," in a man, aged fifty-five, with a history of former excess of alcohol and of an attack of jaundice some years ago. He had a large amount of ascites and was almost in *extremis* when first seen. Paracentesis was performed to give relief, and it did so, but he died two days after. A tumor which was discovered during life was found at the autopsy to consist of the enormously shrunken mesentery, shortened, thickened, and loaded with fat, the small intestines being huddled up compactly together. The omentum was thickened and condensed into the shape of a sausage. The condition was evidently that of a form of chronic peritonitis.

Mr. Barker and Dr. Hale White spoke of similar cases.

Dr. Sidney Phillips related a case of suppurative pylephlebitis with abscess in the spleen and a foreign body in the mesenteric vein, in a man, aged fifty-two, who had had rheumatic fever at the age of seventeen, had suffered from asthma, and had been a free spirit-drinker. The cause of the general suppurative pylephlebitis was in all probability two bristles found at the necropsy in the inferior mesenteric vein; they had probably been swallowed at some previous date, and must have passed, probably as one bristle, through the wall of the intestine, and that of the vein, though no trace could be discovered of their passage. When the spleen became purulent it was so much softened that it gave the erroneous impression that its enlargement had lessened.

Dr. Samuel West described a case of recovery from tuberculous meningitis in a girl, two and one-half years of age. Two children of the same family were taken ill at the same time with similar symptoms. One died, and the autopsy confirmed the diagnosis, so it was presumed the other child also had tubercular meningitis, though it was admitted that the course of the disease was unusual in both cases. Scepticism was expressed by one or two speakers.

Mr. Battle related a case of calculus of the kidney associated with a growth in the renal pelvis. Nephrotomy and, five months later, nephrectomy, were performed. At the first operation it was expected that epithelioma would be found, but there was only a growth of the non-malignant kind, and so it was removed by scraping. The pathologist, however, reported squamous epithelioma. Subsequently the patient returned with clinical signs of innocent growth, but there was severe hemorrhage constantly, and the kidney was removed (August, 1894). He is now in good health. From examination of the kidney the pathologist now considers the case simple papilloma.

The night before last the Royal Society held its soirée. This is the "Ladies' Night," and the exhibition is very popular. Many of the exhibits were exceedingly attractive, but perhaps none excited more admiration than the telephonic communication established for the occasion with Edinburgh, Belfast, and other places. A song, distinctly heard, from the North seemed to some of the visitors to border on the incredible or the supernatural.

OUR PARIS LETTER.

(From our Special Correspondent.)

PATHOLOGY OF THE TONSILS AT THE ACADEMY OF MEDICINE; TUBERCULOSIS AND FOREIGN BODY OF; CALCULUS OF—SUPERNUMERARY URETHRA AND BLADDER—INTERMITTENT FEVER OF PARISIAN ORIGIN—DISEASED VEAL—MONUMENT TO CHARCOT, ETC.

PARIS, June 8, 1895.

THE attention of the Academy of Medicine seems to be just now called to the pathology of the tonsils. Professor Dieulafoy claimed to have proven that the tonsils were often the original seat of tubercular deposit. This he did by means of a series of inoculations of hypertrophied tonsils taken from patients, and the guinea-pigs used in the experiments invariably became tuberculous; he added, "I have examined the question in another aspect and I have endeavored to demonstrate that tuberculosis can have a descending course, that is to say, start from the tonsils and then invade the ganglia, the lymphatic system, and finally the lungs."

Professor Cornil doubted this, the more so as no histological examination of the tissues had been made—this Professor Dieulafoy had considered unnecessary, as the autopsy of the animals inoculated showed such characteristic lesions. Professor Grancher seemed to decide the question by saying that, Professor Dieulafoy had tuberculized guinea-pigs by inoculating them with fragments of hypertrophied tonsils, and if he had not proven the tuberculous nature of the hypertrophy, he had at least directed the attention of the Academy of Medicine to the frequency of the bacillus in the tonsils. The same was true of other mucous membranes, such as the intestinal membranes, which the bacillus of Koch may traverse without lesion at all, and yet go on and produce general lesions in the ganglia.

MM. Combe and Dubourquet-Laborderie presented a calculus of the tonsil about the size of a small nut. They dwelt upon the formation of these calculi, which have for point of departure, or kernel, a foreign body surrounded by mucous deposit, the salts of lime and magnesia, etc., offering an analogy with rhinoliths. Such calculi occasion sometimes severe accidents, but often, on account of the tolerance of the tonsil, they only cause a slight inflammation. Repeated and persistent amygdalitis is almost always caused by their presence in the crypts, where they are the origin of inflammation of the gland and abscesses. The therapeutical indication is antiphlogistic (gargles with carbolic acid as a base, or phenosalyl and saccharin). That failing, resort must be had to surgical treatment, discision, completed by a galvano-cauterization of the wound.

As we know that the tonsils are the starting-point of diphtheria, and as the physiology of these organs has never been made clear, it does seem as if they were only there as a causa morbi. At the same sitting Professor Péan presented a young girl not yet menstruating, with an incontinence of urine having lasted since her birth, which, however, was not congenital, although it appeared to be. The infirmity persisting, the vulva was examined, and a sac-like protuberance discovered in the median line and on the anterior wall of the vagina, beyond the intact hymen. The diagnosis of cystocele was made. A more attentive examination then led Professor Péan to discover the true nature of the case. Introducing his index-finger into the vagina and pressing the tumor, he saw the urine come out, not of the external orifice of the urethra, but out of another opening in the median line 3 mm. below the natural one. Passing a stylet into that opening, a vesical diverticulum was found having a supernumerary urethra. To cure this infirmity the only treatment was to open the supplementary urethra and bladder, and excise them. The incision showed that the accessory urethra was 8 ctm. long, and separated by a thick tissue from the normal urethra. The pocket communicated high up and behind with the bladder. There was no orifice of ureter in the pocket.

Intermittent fever of Parisian origin is certainly a rarity here, but Dr. Ducazal admitted recently into the hospital a soldier suffering with malarial fever, who, never having had a paludal attack before, had contracted the disease at the École Militaire, where he was in garrison, near embankments that had been thrown up on the first works of the Exposition of 1,900. He had an enormous hypertrophy of the spleen that had led the physicians at first to think that he had a tubercular peritonitis and an abdominal abscess. The writer has seen many such cases in Paris, both in the hospitals and in private practice, but never one of Parisian origin—all had come from malarious countries.

It seems that alimentary hygiene is still interesting the committee on sanitation, and M. Vallin has just read a paper on alimentary poisoning caused by veal. This poisoning, or intoxication, as he calls it, is caused by eating veal that has died of infectious diarrhœa or septico-pyæmia. This disease should be noted by veterinarians, and the attention of the authorities directed to the matter.

A monument is soon to be erected to the illustrious Charcot by his fellow-professors, students, friends, and admirers in general throughout France, and it now seems the world. At a recent meeting of the committee under the presidency of Professor Brouardel, it was found that there were actually in the treasury, including subscriptions, 40,000 francs. It is noteworthy that a very large proportion of the subscribers are foreigners. The execution of the work is to be given to M. Falguière—a personal friend of Charcot.

HOW TO GET PRACTICE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Referring to the article, "An Ingenious Medical Man" in the MEDICAL RECORD, June 15th, and credited to the *Medical Press*, I am reminded of a similar device, if not the same out of which the *Press* article has been evolved, attributed to a physician of Montpelier, published in *The Penny Magazine*, London and New York, April 6, 1833, as follows: "Dr. F——, a physician of Montpelier, was in the habit of employing a very ingenious artifice. When he came to a town where he was not known, he pretended to have lost his dog, and ordered the public crier to offer, with beat of drum, a reward of twenty-five louis to whoever should bring it to him. The crier took care to mention all titles and academic honors of the doctor, as well as his place of residence. He soon became the talk of the town. "Do you know," says one," that a famous physician has come here, a very clever fellow; he must be very rich, for he offers twenty-five louis for finding his dog." The dog was not found, but patients were. Also in the same journal the following: "New Way to Get Practice." A poor physician, with plenty of knowledge and no practice, imparted his troubles to one of his friends. "Listen to my advice," says the other, "and follow it. The Café de la Régence is in fashion; I play at chess there every day at two o'clock, when the

crowd is thickest. Come there too ; do not recognize me, and do not speak a word, but seem in a reverie ; take your coffee and always give the waiter the money in a piece of rose-colored paper ; leave the rest to me." The physician followed his advice, and his oddity was soon remarked. His kind friend said to the customers of the coffee-house : "Gentlemen, do not think ill of this man because he seems an oddity ; he is a profound practitioner ; I have known him these fifteen years, and I could tell you of some wonderful cures that he has performed ; but he thinks of nothing but his books, and never speaks except to his patients, which has prevented me from becoming intimate with him ; but if ever I am obliged to keep my bed, he is the doctor for me." The friend went on in this way, varying the style of his panegyric from time to time, till by degrees all his auditors consulted the doctor with the rose-colored paper.

J. T. Howard, M.D.

Washington, D. C., June 18, 1895.

THE TREATMENT OF CHOLERA.

To the Editor of the Medical Record.

Sir : In the synopsis, in a recent issue of the Medical Record, of a paper on cholera, read by Dr. Elmer Lee before the American Medical Association at Baltimore, he is made to say, "Calomel, salol, and quinine have all proven broken reeds."

If Dr. Lee knows of instances in which any considerable number of cholera patients, treated with quinine by the mouth in doses at the rate of about ten grains an hour, have failed to show the best results yet continuously obtained by any treatment known, or that may be hoped of any treatment yet to be devised, it is most certainly a duty he owes to the profession and to humanity that he should make the same known.

As I have shown in this journal and elsewhere, the quinine treatment was killed by intravenous and hypodermatic injections of the drug, and because it failed to reach the germ in the intestinal tract on its route to the kidneys when so administered.

Professor Koch virtually places it highest of all in its control of growth of the germ, and Dr. Graham, who learned his method in the laboratory of that great scientist, demonstrated that in strength of 1 to 2,500 to 1 to 1,000, it kills the germ in time varying from one-half hour to ten minutes.

From 1831 onward, in every epidemic up to and including that of 1873 in the Mississippi Valley, wherever given, in powder or in solution, by the mouth, in doses approximating the above, it has invariably shown the remarkable power in controlling the disease which we would expect from its demonstrated effect upon the germ, and for partial failures the best reasons have been educed. If Antonio Putrelli, Venice, 1831, reduced the mortality to but thirty-three per cent., it was because he gave the remedy in eight-grain pills, which, made up with any of the old excipients, would, with the rapid peristalsis of cholera, rattle down the intestinal tract, to be discharged at the anus like a stone from a catapult. If Dr. Van Meerdervoort (who, Bayard Taylor says, was first to demonstrate anatomy to the Japanese doctors) succeeded in reducing the ordinary mortality of the disease in Nagasaki of sixty to sixty-five per cent. to but 29.22 per cent., it was because of the large number of cases that he attended, an average of over eight hundred yearly in "three different fearful epidemics" (Nagasaki, 1857–63), scattered variously about the city ; he being the only European physician in that city of sixty thousand souls, and rarely called until the disease was well advanced.

In Europe and America I have collected the records of cases to the number of six hundred and seventy-nine of what was undoubtedly cholera of statistic grade of severity with a loss of but thirty-two patients, less than 4.8 per cent. mortality, and almost exactly one-tenth that of the Hamburg epidemic, according to Professor Rumpf, director of hospitals in that city. Moreover, I deny that twelve of these thirty-two fatal cases have any right whatever to a place in these statistics, as they were deaths that occurred in the Tennessee Penitentiary in the epidemic of 1873, after they ceased treating the disease as pernicious intermittent and began with the polytherapy of cholera. Until then, for a period of twenty-six days, with a daily average of fifty-seven patients under treatment, in an epidemic in which 7,356 cases were reported, of whom 3,800 died, in an outbreak that previously to commencement of the quinine treatment had developed a mortality-rate of sixty per cent., and thereafter caused in the city of Nashville, Tenn., 1,000 deaths, upon a dietary of fresh vegetables and sauerkraut, in a Southern penitentiary, there was not a death.

Quinine a broken reed ! Have men in the Ohio Valley yet to demonstrate their capacity for ratiocination along straight lines ?

That there may be other good treatment which will succeed in reducing the mortality in an epidemic of cholera below the fifty per cent. rate is most sincerely to be hoped. That this has not yet been done is apparent, and experimentation in cholera epidemics is costly in human life.

That any treatment contemplating enteroclysis as its method of administration will give the best results in an extensive epidemic, is a matter of grave doubt, to say the least. Fairly good results may accrue in hospital practice where there is every appliance and physicians who have the requisite skill in getting the tannic-acid solution, for instance, beyond the ileo-cæcal valve, as tannic acid has one twenty-fifth the power over the germ awarded by Koch to quinine. Unfortunately, the most of the cholera so far in the United States has been in the Mississippi Valley, and much of it in country practice. Where a physician has to ride ten miles in one direction to see some of his patients, and then as far in another direction to see the rest, I doubt the practicability of this method.

Outside the great cities of our Atlantic seaboard is a stretch of American territory, of which San Francisco is yet some hundreds of miles east of the centre, where, for the most part, such means of administration could not be relied upon.

As to the hydropathic treatment proposed by Dr. Lee, I am glad to furnish a case in point—that of a German, thought to be dying of cholera when it prevailed in this city in 1852. In answer to a supposed last request a pitcher of water was furnished him, which he drank, then another, which he also drank and recovered, to become afterward one of the principal manufacturers of the State. All very well, but for the other German, who under like conditions had his last request also granted—ate, drank, and recovered. The last fellow had a plate of Limburger and a bottle of beer.

There are few things more likely to be vomited in disturbed states of the stomach than water, unless it be warm water. As to soap and water, theory and fact are both against them, as the germ flourishes best in alkaline fluids, and, moreover, both the Ganges and the Elbe consist in the main of water.

Erskine B. Fullerton, M.D.

Columbus O., June 19, 1895.

Science and Christian Science.—A student in one of the colleges for women in a New England town recently informed the faculty that she could no longer attend the lectures on hygiene, as the theories there taught were opposed to the teachings of Christian science.

THE AMERICAN HUMANE ASSOCIATION.

To the Editor of the Medical Record.

Sir: My attention has just been called to an editorial in your issue of June 8th, wherein a similarity of names has led to an error which I trust you will afford me an opportunity to correct. The American Humane Association, which has issued circulars requesting the opinions of members of the medical profession and others regarding vivisection, has nothing whatever to do with the American Humane Education Society of Boston, whose efforts in certain directions you have made the subject of criticism.

May I add that the results of the census of opinions in regard to experimentation upon living animals will hardly justify your very pessimistic conclusions? The inquiry was not instituted to "secure evidence" of any kind, but rather some careful expressions of opinion from those qualified to give them. So far from the replies coming mainly from "those who have taken some fanatical interest in the subject," and who "give their vote for antivivisection," answers have come from some of the leading scientific men in this country and Europe, and the majority thus far received are not from the class you designate. To physicians and surgeons of the highest eminence in this country and Europe, the American Humane Association is indebted not merely for signatures to some one of its statements, but for letters carefully defining their position in regard to the whole question of restriction or non-restriction. Certainly no American physician need hesitate to have his views on any subject contrasted with those of Sir John Eric Erichsen, Sir Joseph Fayrer, Dr. Forbes Winslow, and Dr. Robert Braithwaite.

Albert Leffingwell, M.D.

Cambridge, Mass., June 20, 1895.

SOME STATISTICS ON PARESIS.

To the Editor of the Medical Record

Sir: Your editorial of June 1st, giving rural district returns as to the number of cases of paresis, and its frequency compared with that of former years, may be supplemented with similar returns from the male asylum at Ward's Island, New York City.

The occurrence, or rather the recognition, of paresis has apparently taken place rather abruptly during the year 1873; previous to this time "ramollissement," "peri-encephalitis," etc., obscure and bewilder occasional accurate diagnosis so as to make statistics unreliable. For the past twenty years there seems to have been an almost mechanical uniformity in ratio between paresis and all other forms of insanity.

During the period from 1875 to 1895 the number of cases of paresis (diagnosed at death) was as follows:

1875 to 1880, total deaths,	658;	paretics,	215,	or 32	per cent.
1880 " 1885, " "	861;	"	314,	" 36	" "
1885 " 1890, " "	1,140;	"	397,	" 34	" "
1890 " 1891, " "	233;	"	78,	" 32	" "
1891 " 1892, " "	290;	"	87,	" 30	" "
1892 " 1893, " "	293;	"	92,	" 32	" "
1893 " 1894, " "	293;	"	88,	" 33	" "
1894 " 1895, " "	287;	"	95,	" 33	" "

Thus giving out of a total of 4,025 deaths, 1,366 cases of paresis, or about thirty-three per cent. of deaths from all forms of insanity.

So much for the dead who died of paresis, and these alone rather point to a previous non-recognition than an increased frequency.

Of the admissions, the past five years show the same uniform progress. In 4,628 male admissions, there were 705 cases of paresis, or about fifteen per cent. The death records of this disease reveal a remarkable range in duration, the maximum being thirty-five years. The oldest person at death, seventy-nine; the youngest, twenty-two. The number of syphilitics, 185. Socially the married are to the single, as three to one: to the widowed, as twelve to one; while the divorced stand as one man.

Louis C. Pettit, M.D.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 29, 1895.

Typhoid fever	8	5
Scarlet fever	55	5
Cerebro-spinal meningitis	2	0
Measles	251	25
Diphtheria	243	27

The License to Practise Medicine in the State of New York.—The Law Now in Force.—We present our readers with the full text of the Medical Law of the State of New York, with all amendments to date:

Laws of New York, 1893, ch. 661.—Previous laws relating to practice of medicine were repealed May 9, 1893, when this law took effect.

§ 140. Qualifications.—No person shall practise medicine after September 1, 1891, unless previously registered and legally authorized or unless licensed by the regents and registered as required by this article; nor shall any person practise medicine who has ever been convicted of a felony by any court, or whose authority to practise is suspended or revoked by the regents on recommendation of a State board.

§ 141. State Boards of Medical Examiners.—There shall continue to be three separate State boards of medical examiners of seven members each, each of whom shall hold office for three years from August 1st of the year in which appointed. One board shall represent the Medical Society of the State of New York, one the Homœopathic Medical Society of the State of New York, and one the Eclectic Medical Society of the State of New York. Each of these three societies shall at each annual meeting nominate twice the number of examiners to be appointed in that year on the board representing it. The names of such nominees shall be annually transmitted under seal by the president and secretary prior to May 1st to the regents, who shall, prior to August 1st, appoint from such lists the examiners required to fill any vacancies that will occur from expiration of term on August 1st. Any other vacancy, however occurring, shall likewise be filled by the regents for the unexpired term. Each nominee before appointment shall furnish to the regents proof that he has received the degree of doctor of medicine from some registered medical school and that he has legally practised medicine in this State for at least five years. If no nominees are legally before them from a society the regents may appoint from members in good standing of such society without restriction. The regents may remove any examiner for misconduct, incapacity, or neglect of duty.

§ 142. Certificate of Appointment; Oath; Powers.—Every medical examiner shall receive a certificate of appointment from the regents, and before beginning his term of office shall file with the Secretary of State the constitutional oath of office. Each board, or any committee thereof, may take testimony and proofs concerning all matters within its jurisdiction. Each board may, subject to the regents' approval, make all by-laws and rules not inconsistent with law needed in performing its duties; but no by-law or rule

by which more than a majority vote is required for any specified action by the board shall be amended, suspended, or repealed by a smaller vote than that required for action thereunder.

§ 143. Expenses.—From the fees provided by this article the regents may pay all proper expenses incurred by its provisions, except compensation to medical examiners ; and any surplus at the end of any academic year shall be apportioned among the three boards *pro rata* according to the number of candidates whose answer papers have been marked by each.

§ 144 Officers ; Meetings ; Quorum ; Committees.—Each board shall annually elect from its members a president and a secretary for the academic year, and shall hold one or more meetings each year pursuant to call of the regents, who may also call joint meetings of the three boards or of their officers. At any meeting a majority shall constitute a quorum ; but questions prepared by the boards may be grouped and edited, or answer papers of candidates may be examined and marked by committees duly authorized by the boards and by the regents.

§ 145. Admission to Examination.—The regents shall admit to examination any candidate who pays a fee of $25 and submits satisfactory evidence, verified by oath if required, that he : 1. Is more than twenty-one years of age ; 2, is of good moral character ; 3, has the general education required in all cases after August 1, 1895, preliminary to receiving the degree of bachelor or doctor of medicine in this State ; 4, has studied medicine not less than three full years, including three satisfactory courses, in three different academic years, in a medical school registered as maintaining at the time a satisfactory standard ; 5, has either received the degree of bachelor or doctor of medicine from some registered medical school, or a diploma or license conferring full right to practise medicine in some foreign country.

The degree of bachelor or doctor of medicine shall not be conferred in this State before the candidate has filed with the institution conferring it the certificate of the regents that three years before the date of the degree, or before or during his first year of medical study in this State, he had either graduated from a registered college or satisfactorily completed not less than a three years' academic course in a registered academy or high school ; or had a preliminary education considered and accepted by the regents as fully equivalent ; or had passed regents' examinations in arithmetic, elementary English, geography, spelling, United States history, English composition, and physics. Students who had matriculated in a New York medical school before June 5, 1890, shall be exempt from this preliminary education requirement, provided the degree be conferred before August 1, 1895. The regents may in their discretion accept as the equivalent for any part of the third and fourth requirement, evidence of five or more years' reputable practice of medicine, provided that such substitution be specified in the license.

§ 146. Questions.—Each board shall submit to the regents, as required, lists of suitable questions for thorough examination in anatomy, physiology, and hygiene, chemistry, surgery, obstetrics, pathology and diagnosis, and therapeutics including practice and materia medica. From these lists the regents shall prepare question papers for all these subjects, which at any examination shall be the same for all candidates, except that in therapeutics, practice, and materia medica all the questions submitted to any candidate shall be chosen from those prepared by the board selected by that candidate, and shall be in harmony with the tenets of that school as determined by its State board of medical examiners.

§ 147. Examinations and Reports.—Examinations for license shall be given in at least four convenient places in this State, and at least four times annually, in accordance with the regents' rules, and shall be exclusively in writing and in English. Each examination shall be conducted by a regents' examiner, who shall not be one of the medical examiners. At the close of each examination the regents' examiner in charge shall deliver the questions and answer papers to the board selected by each candidate, or to its duly authorized committee, and such board, without unnecessary delay, shall examine and mark the answers and transmit to the regents an official report, signed by its president and secretary, stating the standing of each candidate in each branch, his general average, and whether the board recommends that a license be granted. Such report shall include the questions and answers and shall be filed in the public records of the University. If a candidate fails on first examination, he may, after not less than six months' further study, have a second examination without fee. If the failure is from illness or other cause satisfactory to the regents, they may waive the required six months' study.

§ 148. Licenses.—On receiving from a State board an official report that an applicant has successfully passed the examinations and is recommended for license, the regents shall issue to him, if in their judgment he is duly qualified therefor, a license to practise medicine. Every license shall be issued by the University under seal and shall be signed by each acting medical examiner of the board selected and by the officer of the University who approved the credential which admitted the candidate to examination, and shall state that the licensee has given satisfactory evidence of fitness as to age, character, preliminary and medical education, and all other matters required by law, and that after full examination he has been found properly qualified to practise. Applicants examined and licensed by other State examining boards registered by the regents as maintaining standards not lower than those provided by this article, and applicants who matriculated in a New York State medical school before June 5, 1890, and who receive the degree M.D. from a registered medical school before August 1, 1895, may without further examination, on payment of $10 to the regents and on submitting such evidence as they may require, receive from them an indorsement of their licenses or diplomas conferring all rights and privileges of a regents' license issued after examination.

If any person, whose registration is not legal because of some error, misunderstanding, or unintentional omission, shall submit satisfactory proof that he had all requirements prescribed by law at the time of his imperfect registration and was entitled to be legally registered, he may, on unanimous recommendation of a State board of medical examiners, receive from the regents under seal a certificate of the facts, which may be registered by any county clerk and shall make valid the previous imperfect registration.

Before any license is issued it shall be numbered and recorded in a book kept in the regents' office, and its number shall be noted in the license. This record shall be open to public inspection, and in all legal proceedings shall have the same weight as evidence that is given to a record of conveyance of land.

§ 149. Registry.—Every license to practise medicine shall, before the licensee begins practice thereunder, be registered in a book kept in the clerk's office of the county where such practice is to be carried on, with name, residence, place and date of birth, and source, number, and date of his license to practise. Before registering, each licensee shall file, to be kept in a bound volume in the county clerk's office, an affidavit of the above facts, and also that he is the person named in such license, and had, before receiving the same, complied with all requisites as to attendance, terms, and amount of study and examinations required by law and the rules of the University as preliminary to the conferment thereof ; that no money was paid for such license, except the regular fees paid by all appli-

cants therefor; that no fraud, misrepresentations, or mistake in any material regard was employed by anyone or occurred in order that such license should be conferred. Every license, or if lost, a copy thereof legally certified so as to be admissible as evidence, or a duly attested transcript of the record of its conferment shall, before registering, be exhibited to the county clerk, who, only in case it was issued or indorsed as a license under seal by the regents, shall indorse or stamp on it the date and his name, preceded by the words: "Registered as authority to practise medicine in the clerk's office of —— county." The clerk shall thereupon give to every physician so registered a transcript of the entries in the register, with a certificate under seal that he has filed the prescribed affidavit. The licensee shall pay to the county clerk a total fee of $1 for registration, affidavit, and certificate.

§ 150. Registry in Another County.—A practising physician having registered a lawful authority to practise medicine in one county, and removing such practice or part thereof to another county, or regularly engaging in practice or opening an office in another county, shall show, or send by registered mail to the clerk of such other county, his certificate of registration. If such certificate clearly shows that the original registration was of an authority issued under seal by the regents, or if the certificate itself is indorsed by the regents as entitled to registration, the clerk shall thereupon register the applicant in the latter county, on receipt of a fee of twenty-five cents, and shall stamp or indorse on such certificate the date and his name preceded by the words: "Registered also in . . . county," and return the certificate to the applicant.

§ 151. Certificate Presumptive Evidence; Unauthorized Registration and License Prohibited.—Every unrevoked certificate and indorsement of registry, made as provided in this article, shall be presumptive evidence in all courts and places, that the person named therein is legally registered. Hereafter no person shall register any authority to practise medicine unless it has been issued or indorsed as a license by the regents. No such registration shall be valid unless the authority registered constituted at the time of registration, a license under the laws of the State then in force. No diploma or license conferred on a person not actually in attendance at the lectures, instruction, and examinations of the school conferring the same, or not possessed at the time of its conferment, of the requirements then demanded of medical students in this State as a condition of their being licensed so to practise, and no registration not in accordance with this article shall be lawful authority to practise medicine, nor shall the degree of doctor of medicine be conferred *causa honoris* or *ad eundum*, nor if previously conferred shall it be a qualification for such practice.

§ 152. Construction of this Article.—This article shall not be construed to affect commissioned medical officers serving in the United States army, navy, or marine hospital service, while so commissioned; or any one while actually serving on the resident medical staff of any legally incorporated hospital; or any legally registered dentist exclusively engaged in practising dentistry; or any manufacturer of artificial eyes, limbs, or orthopedic instruments or trusses in fitting such instruments on persons in need thereof; or any lawfully qualified physician in other States or counties meeting legally registered physicians in this State in consultation; or any physician residing on a border of a neighboring State and duly authorized under the laws thereof to practise medicine therein, whose practice extends into this State, and who does not open an office or appoint a place to meet patients or receive calls within this State; or any physician duly registered in one county called to attend isolated cases in another county, but not residing or habitually practising therein. This article shall be construed to repeal all acts or parts of acts authorizing conferment of any degree in medicine, *causa honoris* or *ad eundum* or otherwise than on students duly graduated after satisfactory completion of a preliminary and medical course not less than that required by this article, as a condition of license.

§ 153. Penalties and their Collection.—Every person who shall practise medicine within this State, without lawful registration or in violation of any provision of this article, shall forfeit to the county wherein such person shall so practise or in which any such violation shall be committed, $50 for every such violation and for every day of such unlawful practice, and any incorporated medical society of the State or any county medical society of such county entitled to representation in a State society, may bring an action in the name of such county for the collection of such penalties, and the expense incurred by any such society in such prosecution, including necessary counsel fees, may be retained by such society out of the penalties so collected, and the residue, if any, shall be paid into the county treasury. Any person who shall practise medicine under a false or assumed name, or who shall falsely personate another practitioner of a like or different name, shall be guilty of a felony; and any person guilty of violating any of the other provisions of this act, not otherwise specifically punished herein, or who shall buy, sell, or fraudulently obtain any medical diploma, license, record, or registration, or who shall aid or abet such buying, selling, or fraudulently obtaining, or who shall practise medicine under cover of a diploma or license illegally obtained, or signed or issued unlawfully or under fraudulent representations, or mistake of fact in material regard, or who, after conviction of a felony, shall attempt to practise medicine, and any person who shall append the letters M. D. to his or her name, or shall assume or advertise the title of doctor in such a manner as to convey the impression that he is a lawful practitioner of medicine or any of its branches without having legally received the medical degree, shall be guilty of a misdemeanor, and on conviction thereof shall be punished by a fine of not less than $250, or imprisonment for six months for the first offence, and on conviction of a subsequent offence, by a fine of not less than $500, or imprisonment for not less than one year, or by both fine and imprisonment.

NEW BOOKS RECEIVED.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it, which in the judgment of its editor will not be of interest to its readers.*

On Some Symptoms which Stimulate Disease of the Pelvic Organs in Women, and their Treatment by Allo Piesto-Myo-Kinetics (Massage) and by Auto-Piesto-Myo-Kinetics (Self-movements of Muscles under Pressure). SHALL INSANE CRIMINALS BE IMPRISONED OR PUT TO DEATH?

By J. B. RANSOM, M.D.,

CLINTON, N. Y.

PHYSICIAN TO CLINTON PRISON.

Such assassinations as those of Czar Alexander II., President Garfield, President Carnot, and Mayor Harrison, and the many attempts at wholesale assassinations which have occurred within a score of years, together with numerous horrifying cases of homicide—all correlative with the evolution of the modern crank—have stirred the whole social fabric to a deep feeling of concern as to what disposal is to be made of this so-called "crank element;" and, naturally enough, developed an exasperated public sentiment, sweeping in its conclusions, swift to condemn, and eager to execute.

Inasmuch as medical expert testimony has figured so largely in many of the trials of these culprits, it thus becomes a necessary and profitable question for us to consider as medical men. I shall not attempt, in a paper of this length, to go minutely into the relations which criminal life and criminal acts bear to brain conditions, but will limit myself to the consideration of medical expert testimony, particularly in cases of homicide, where insanity is made the plea of the defence.

Assuming that this State, like all civilized countries of the earth, recognizes that law of common justice and right—the exemption from, or mitigation of, the penalty consequent upon the commission of crime by the mentally irresponsible—I shall base all my conclusions upon this assumption, and upon the belief that society at large does not voice the inhuman and brutal sentiment which we hear so often expressed, that the unfortunate creature

"Who, by the hand of nature marked,"

is thus made the helpless victim of his own physical environment, should be imprisoned or put out of existence with no reference whatsoever to his responsibility. There is something too revolting, too barbarous, in this sentiment of prostituting justice to so repulsive an end, and is indefensible from any medical or moral stand-point.

I shall, then, assume that when an individual is found to be mentally irresponsible under the law, he should not be treated as a responsible criminal; in other words, that such an irresponsible being should not be sent to either a prison proper or be subject to execution.

As to what is to be done with this class of criminals is not within the sphere of this paper, but could well form the subject of an ampler one. Incidentally I should say, however, that the conditions are suggestive of restrictions in immigration, and the establishing of institutions especially designed for the care of degenerate criminals, and the enactment of adequate laws permitting their apprehension, and, if necessary, lifelong detention in such institutions. In this way only will their menace to public safety be abated. Certainly there is little deterrent benefit to be derived, or safety to be secured, by the execution of the irresponsible crank, for numbers of this kind will aspire to fulfil his mission and share his diabolical glory—if I may so express it—even at the risk of such a fate. This savors too much of the philosophy of "locking the barn-door after the horse is stolen." Apprehension, not execution, is what we want, and is best calculated to mitigate this evil.

From a considerable experience and from different sources of information I am led to believe that our present methods of apprehending and trying criminals are very much at fault, especially with reference to their mental condition. It is a fact that our prisons and penitentiaries have a large number of individuals confined therein who are mentally irresponsible, and who were undoubtedly so at the time of the commission of their crimes. In these institutions you will find all grades of the degenerate, from the imbecile up to the paranoiac, and whose crimes range from a larceny to homicide. My knowledge of those doing life-sentence for homicide has convinced me that many are of unsound mind, and I have committed a number of them to the Asylum for Insane Criminals. When we come to the death penalty, even here—in more than one case—it has been my unpleasant experience to discover meningeal adhesions over atrophic and diseased brain areas. I am making no plea for the responsible criminal, nor for the abolition of capital punishment. I am simply stating a series of facts, having their causation in conditions which I believe to be largely due to the inability of the courts to decide upon the responsibility of the accused under the law, and, through the failure of medical expert testimony—as at present introduced—to determine the mental status of criminals under indictment and to properly differentiate and classify them. In cases where the defence does not make mental incapacity a plea, the matter is left wholly to the judge to decide, and he, either through inability to pass upon such a question, or indisposition to raise the question, too often leaves it to the prison authorities to decide as to a man's mental condition. If, on the other hand, a plea for the defence is made on the ground of insanity, then the whole of the cumbersome and unwieldy machinery of medical expert testimony is set in motion, and this nightmare of confusion is precipitated upon the court.

I do not wish it to be understood that I am making a wholesale condemnation of medical expert testimony, nor that I second all of the severe animadversions made by judges and writers on medical jurisprudence, many of which are rash and altogether too sweeping in their condemnation. What I would condemn is the manner and method of the introduction of medical expert testimony and the helplessness of the courts in protecting themselves against the admission of a sort of "so-called" medical expert testimony, based either upon ignorance and prejudice, or prompted by venality and the love of notoriety.

Ordroneaux as early as 1874 said: "In fact, the calling of experts has now come to be regarded as the signal for the display of forensic pyrotechnics, beneath whose smoke and lurid glare law, common-sense, and unalloyed justice are swept away in a whirlwind of muddy metaphysics. It is needless to say, however, that all honest men look upon this as a judicial farce, and a degradation of the ethics of jurisprudence."

All experts are not thus, and it is a well-known fact that there are many competent and sincerely just ones. Neither are we unmindful of the fact that there are, and always must be, serious difficulties in the way of conclusively fixing the mental status of an accused individual. A careful study, however, of the last century's criminal trials, goes to show that gross injustice has been done in many cases; that ignorance and prejudice have too often proved too much for intelligent facts; that in many of these trials the medical expert testimony has been an exhibition of contradictions and absurdities which could only be accounted for on the grounds above mentioned, or its servile submission to public clamor, which, carried to a logical and more radical sequence, simply means Lynch law. In certain forms of insanity this seems to have been especially true. There seems also to have been an almost total want of recognition by the courts of certain mental defects, constituting a most dangerous and hopeless form of mental disease, to which I shall refer further on.

To better illustrate the above I will call your attention to two cases, which on account of their recent date and wide-spread publication, are still fresh in your minds, and in which medical expert testimony failed to arrive at conclusions based upon facts:

Case I.—Patrick Joseph Eugene Prendergast, a newsboy, aged twenty-six, who shot Mayor Harrison, of Chicago, in December, 1893, and for the history of whose case I am greatly indebted to Drs. Bannister[1] and Brower,[2] who wrote up his case thoroughly. The assassination took place just as the Mayor had successfully closed an important function of the Columbian Exposition, and so great was the shock that it was almost impossible, even for months afterward, to find a person who could dispassionately discuss the mental state of this murderer. So familiar are the details of this crime that it is unnecessary to speak of them here.

"The case was clearly one for medical expert testimony to decide upon, and the State's attorney originally called six physicians to investigate the mental condition of this man. Five of them had large experience in the treatment of the insane; the sixth was a surgeon of considerable local reputation, making no claim, however, to expert knowledge of insanity. The five physicians reached the conclusion that the man was

Fig. 1.—Prendergast.

insane. The surgeon reached the opposite. Nevertheless the public was treated to another judicial murder."

Prendergast's history well sustains the conclusion of the five physicians. "He was born in Ireland, April 18, 1868. His paternal grandfather died insane; his mother had repeated attacks of hysterics; his father died of consumption. When four years old Prendergast received a severe injury to the head by falling from a bench, and was unconscious for a considerable length of time, vomiting almost constantly for four weeks afterward. He was a peculiar child; solitary in his habits; irritable; easily excited; had a poor memory; was dull and backward in school. At puberty he became distrustful and antagonistic to his parents. At sixteen years of age he left his home on account of imaginary persecutions. At eighteen he had exaggerated opinions of his own ability; he became a fanatic on the single-tax notion; professing to be a Roman Catholic he yet criticised the Pope's administration of the Church; he wrote prayers which he claimed were efficacious against certain calamities; he claimed that his prayers and electioneering elected Mayor Harrison, and that therefore he should receive the office of Corporation Counsel, and, that once appointed, he simply needed the authority of this office to speedily elevate the tracks of the railroads, so as to put a stop to the slaughter of life at the present railroad crossings in that city. When the position was filled by a skilful lawyer, he called repeatedly upon him, and demanded him to vacate the office, to which he, Prendergast, was alone entitled. During the discussion of the Silver Bill in Congress, he wrote numerous postal cards to Congressmen instructing them how to vote, and claimed that his prayers, and not their votes, passed the measure."[1] In a very deliberate manner he shot the Mayor, and then proceeded as rapidly as possible to the police station and told the officials there that he had shot Mayor Harrison.

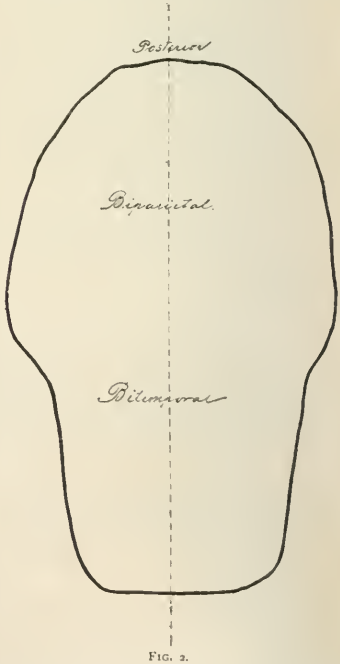

Fig. 2.

You will readily see by the picture of this man that there appears to be an unreasonable development of the lower jaw. Upon a closer examination, however, there is found an arrest of development of the bones of the face and upper jaw, extending from the upper

[1] H. M. Bannister, A.M., M.D., late Senior Physician Illinois Eastern Hospital for the Insane.

[2] H. Brower, M.D., one of the experts called by the State's attorney to examine the mental status of Prendergast.

[1] Quotations from Dr. Brower's paper on Prendergast.

border of the orbit down, producing concavity. This arrest of development carries the nose and face in

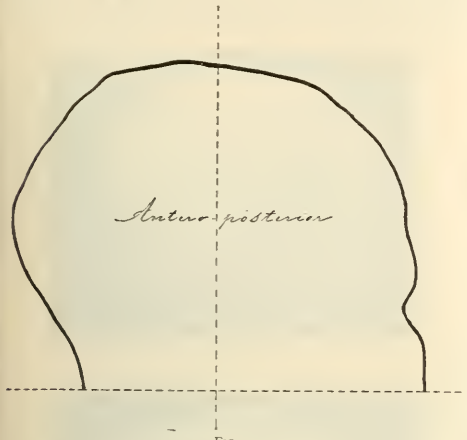

Fig. 3.

from one-quarter to three-quarters of an inch from its normal position. As a result of the arrest of development of the upper jaw, certain forms of irregularities of

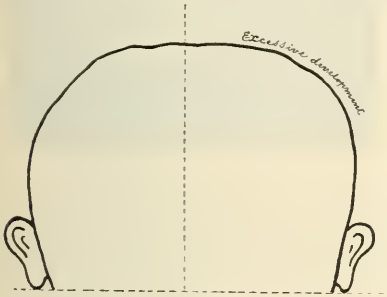

Fig. 4.

the teeth occur, as you will notice on Fig. 5.[1] On the photograph you will further notice the typical degenerate ear of Morel. Other structures of the body, such

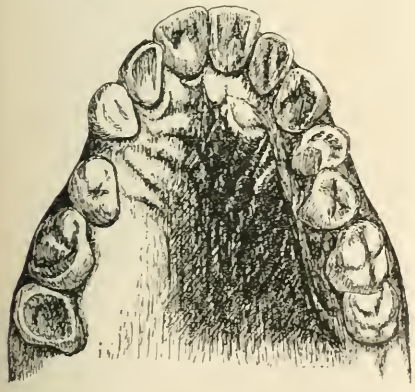

Fig. 5.

as hair, skin, and lymphatic glands, were abnormal. These arrests of development occurred early in life, before the sixth year, and were due to defects in the cell-structure of the brain governing then utrition of these parts.

Figs. 2, 3, and 4, show the outlines of the skull. Like the facial bones they are very remarkable. You will notice that the antero-posterior and biparietal diameters are not very much of a departure from the normal type. The bitemporal diameter, on the contrary, is most unusually so. Such a remarkable arrest of development of the frontal region of the skull, as the outlines on Figs. 2 and 3 show, indicates that the higher intellectual faculties and consequent self-control are very deficient. These same figures also show the unusually large development of the lower mental faculties. Fig. 4 shows a marked depression on the top of the head. I chiefly wish to call your attention to the small intellectual and controlling power of such a developed brain. These facts go clearly to show that this man was a creature of impulses, and not of reason. In other words, impulse was the mastering element, the moving force of his nature, and he knew or could know no law of volition. Prendergast evidently belonged to that class of degenerates called paranoiacs, fitting closely the descriptions of Gray, Régis, and Kirchhoff,[1] who attribute to them self-exaltation; systematized progressive delusions; tendencies toward political homicides, apparently premeditated, well calculated, and consistent with their delusions. Such persons need but an inspiration to develop delusional impulses, which are executed with astonishing rapidity, decisiveness, and fiendish cunning.

This man labored under the delusion that it was a divinely imposed duty for him to slay the Mayor, and to see that track-elevation might be effected, and lives accordingly saved. This was emphasized by his eagerness to give himself up to the officers of the law, and the assertion that he would do the same thing over again, believing "that the God who had commissioned him would have him under his special care." It seems convincing enough to the average mind that this man was insane, and yet, in spite of this, and the fact—as before stated—that five medical experts out of six testified that he was insane, it proved to be insufficient to protect him from the injustice which public clamor visited upon him, and he was executed.

Fig. 6.—Lizzie Halliday.

Case II.—Mrs. Lizzie Halliday, the Sullivan County triple murderess. This woman's case and trial are of so recent date that it will be unnecessary to enter into details with reference to them. She was born in Ire-

[1] The photographs and drawings illustrating this case are all copied from Dr. Brower's paper on Prendergast.

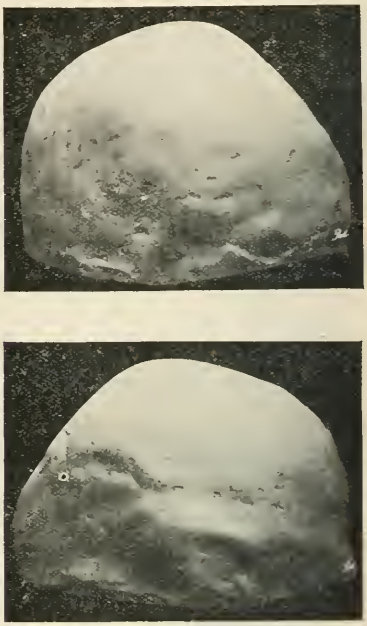
land, under the name of McNally, and came to this country in 1867. She is now thirty-six years of age; five feet and two inches in height. Her girlhood was

Fig. 7.

uneventful, unless that she was of a more than usually irritable temper and rather capricious (see Fig. 8). The cast, as illustrated by Figs. 9 and 10, and roughly made by myself, together with Figs. 6, 7, and 11, give the outlines of Mrs. Halliday's skull.[1] It is mark-

Fig. 8.—Margaret McNally.

edly asymmetrical. Her head is high and somewhat tapering, as will be seen in Figs. 6 and 7. I wish particularly to call your attention to Fig. 11, showing the circumference of the head. It is one of most unusual shape, inasmuch as the right side seems to have been forced backward, and the left forward, thus making an irregular elliptic curve. The peculiar prominence in the left frontal region and the excessive prominence of the right occipital are very noticeable, and attracted my attention when I first examined her. There is a marked flattening in the right occipito-parietal region, and also an excessive development of the right side over that of the left, which is exactly opposite to the normal head. The excessive development over the paracentral lobe is also very noticeable. In the greater fulness of the right side there is a similarity between this head and that of Prendergast.



Figs. 9 and 10.—Casts of Mrs Halliday's head.

Régis says that in chronic insanities, contrary to the usual rule, the right hemisphere of the brain very often weighs more than the left. My observations in the examination of several thousand criminals have led me to believe that, as a rule, when in the inherent crim-

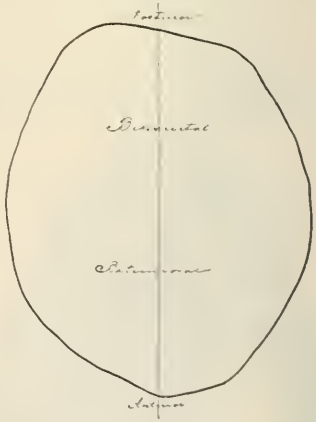


Fig. 11.

inal the right side of the cranium (that is, the right hemisphere of the brain) is in an excessive development over the left, especially where there is a marked fulness over the paracentral lobe, the possessor's impulses lead toward homicide. I have repeatedly been able to place my hand upon this part of the head of criminals and designate their crimes to be either assault or homicide, without any previous knowledge of their

[1] The cast was made as follows: The hair having been evenly pasted down to the scalp, rubber tissue was carefully fitted over the hair, and pressed firmly down. A diaphragm was then placed around the head at a level with the eyebrows in front, and immediately below the base of the cranium posteriorly, and a mould made in the regular way. Subsequent expert palpation demonstrated its correctness.

history or themselves. Both Figs. 4 and 7 show this excessive development, which in Lizzie Halliday (Fig. 7) is more marked.

A look at these photographs of her, which were taken while she was under confinement in Clinton Prison, shows: Nose coarse and disproportionately large;

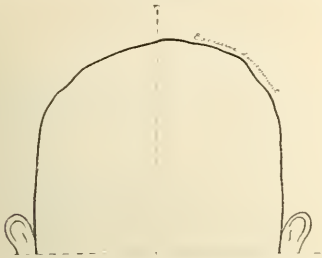

Fig. 12.

bridge flat and upturned; malars and superciliary arches prominent, mouth large, lips medium thickness, teeth fairly regular, etc. Space will not permit me to enter into a description of this woman's history and symptoms from girlhood until the time of her arrest, although it is exceedingly interesting. It is, however,

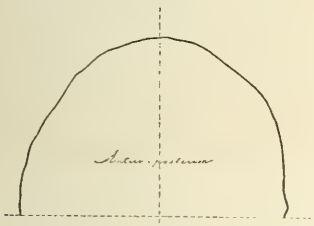

Fig. 13.

elaborately described by Dr. Blumer[1] in a paper read before the Kings County Medical Society on September 18, 1894, and I am greatly indebted to him for many valuable suggestions and quotations in the preparation of this paper. I will therefore content myself by stating that careful and painstaking research, previous to the time of the commission of the triple murder, for which she was tried and sentenced, has shown that she had always been erratic and peculiar beyond comprehension; that she had married six times—in every instance moved by some unexplainable caprice—and that she had been in two asylums in this State. There is also evidence going to show that this woman for the whole period from the time of the commission of the triple murder until her trial gave unmistakable symptoms of insanity.

She was received at Clinton Prison on June 29, 1894, and on that date came under my professional care, remaining in my charge until July 23d, same year. A careful record of observations was made daily during that time by myself and attendants.

Chief among the physical symptoms noted were rapid pulse, averaging over 100; extreme emaciation; refusal of food, necessitating forced feeding; diabetic symptoms (quantitative analysis of her urine on July 13th showing 4.5 per cent. of glucose); excessive menstrual flow; at these times she was much more violent and difficult to control; a complete anæsthesia even of the most sensitive areas of the skin, eyeballs, and nose (this analgesic condition was so complete that flies crawling over her face were never brushed away, and that tests made with the knife-point and the application of the lighted fuse failed to produce the slightest reflex, or the cessation for an instant of her incoherent jargon); drooling of larger quantities of glairy mucus from the nose and mouth; her walk was shuffling, irregular, and uncertain, and she could not maintain her equilibrium with her eyes closed.

The mental symptoms noted were: Illusions and hallucinations of sight and sound; she was violent and noisy; her habits were extremely filthy; she exhibited obsessions (or irresistible propensities), such as the ejaculation of vile language without provocation, agonizing fears of crossing a river when taken to and from her cell, constant repetition of the number 13, etc.

The following extract from Dr. Blumer's paper illustrates vividly the above: "The patient was crouching in a corner of her cell with her face turned to the wall, muttering and hallooing incoherently. When brought into the corridor she offered resistance, crying, 'Don't let me go by the river.' Her ears and nostrils were stuffed with bits of dress material. When forcibly seated in a chair she began to pick at her clothing, to spit, to stamp on the floor, and, when not restrained, pounded her thighs violently with her fists. She paid no attention to her examiners, and could not be induced to answer questions. The following were some of her incoherent mutterings, taken down at the time: 'Manure. Nicodemus. Pitchforks. Don't you stay here. No! I don't want you. Yes! You did. You took my baby. Thirteen and fourteen o'clock. Snow and bullfrogs. Take the little dress out of the drawer, and bring my little Isabella. Take them snakes away. Nineteen cords charcoal. Don't throw that over me. I can't eat that sawdust. You have got small-pox in your heels. She broke a spine of my ribs. You have got that bear sewed up in me,'" etc.

These symptoms, taken in connection with the configuration of her head unmistakably place her with that class of degenerates described by the French alienists as the phrenastheniacs, in other words, a creature of irresistible impulses, feebleness of will, yet possessed of a degree of conscious and reasoning power, and whose dominant morbid tendencies are to private murder.

Mrs. Halliday was such a being. With intelligence and reason sufficient to plan and execute, but without power to choose, without moral feeling, unknown to remorse, she only needed an exciting cause, such as some disturbance of the reproductive organs, to set in motion an impulse, which, resisted it may be for a time, yet gathering in intensity, becomes too strong for volition, the demoniacal impulse is freed from its domination, and the fiendish act is perpetrated.[1]

The picture is complete, and even if the symptoms alleged to have been feigned by the experts for the prosecution, were so, the physical symptoms above enumerated at least admit of no intelligent doubt as to her insanity. Notwithstanding this, and the fact that two expert alienists, Drs. Allison and Talcott,[2] under whose charge she had been when in asylum, testified that she was insane, this woman, principally upon the testimony of one so-called expert, was sentenced to be executed, and had it not been for the executive, who in clemency appointed the commission that declared her insane, another name would have been added to the list of judicial homicides.[3]

We have seen by the above that both Prendergast and Lizzie Halliday belonged to a class of degenerate criminals, and were both suffering from what may be termed conscious-impulsive insanity, and that both cases were decided by the courts through the agency of certain medical expert testimony, adjusting itself to suit the demand of an excited and clamorous public,

[1] G. A. Blumer, M.D., Superintendent of the State Asylum for the Insane at Utica, N. Y.

[1] H. E. Allison, M.D., Superintendent of the State Asylum for Insane Criminals at Matteawan, and who now has her in charge, believes that her crimes have been committed when she was or had recently been pregnant, and there is much to substantiate this view.

[2] S. H. Talcott, M.D., Superintendent of the Middletown Asylum.

[3] The members of this commission were Drs. G. A. Blumer, J. M. Lee, and J. D. Spencer.

in direct opposition to what we have seen to be the facts. In both cases the error seems to have arisen from a common misapprehension by the courts of just what mental responsibility means. The courts have repeatedly held that the question to decide as touching a man's mental responsibility under the law, is his ability to distinguish between right and wrong, that is, to be able to understand his moral and legal responsibility. While this applies to certain forms of insanity it is not all that is necessary in the way of a test, nor does it cover the whole ground, for it will be readily seen that by the application of this test alone to the cases above cited a rank injustice was done. The question to decide in any given case of insanity is not alone as to whether the mental perceptions admit the knowledge of the right or wrong, for which a person is held to trial, for it may be a question of the individual's power to control his impulse, a question of volition, not of a nice adjustment of moral equities. Consciousness must not be confounded with control, because, as we have seen, an insane person may be perfectly conscious of his acts, conscious of his responsibility to the law, conscious of the penalty, conscious to a degree, enabling him to use his powers of cunning to avoid the infliction of penalty, and yet in no way more responsible for the act than would be the man who, hurled from the top of some high building, falls upon a passing pedestrian and crushes him to death.

The power of controlling the acts is more or less the essential factor in insanity and irresponsibility, and more so than is the knowledge of their nature and consequences. Insanity is a disease, and not a legal question. We should not allow ourselves to be misled by the shrewd tactics of the manipulators of the law, or be influenced by the popular distrust of the plea of insanity as a defence for crime, in common parlance called "The Insanity Dodge."

If it is conceded that insanity is to lessen responsibility and to mitigate punishment, why then there is no half-way ground to be taken. This mantle of attenuation cannot justly cover only a certain type of the mentally deficient, but must extend itself over all forms and types, the inherently deficient and the degenerate as well as the demented and the melancholic. The fact that the law does not afford protection for the former class, who need it so much more than the latter against an exasperated public sentiment, is due, as before intimated, to the failure of medical expert testimony, as at present introduced, to so protect them, and in the light of these cases there has apparently been little, if any, advance made toward a more reasonable and more definite method of introducing such testimony.

It is true that occasionally a step in the right direction is taken in eliminating much that is objectionable and harmful in such trials, as was the case in a recent trial which took place in the District of Columbia.[1] But to my knowledge nothing consistent with an improved revision of the whole system of medical expert testimony has been undertaken. The question at once arises, By whom shall this needed reform be undertaken, and to whom shall we look for a first movement in the right direction? If we listen intently we may hear the indefinable mutterings of an arousing public sentiment in this regard, and I firmly believe that the first indictment lodged by that most exacting of tribunals, an awakened public mind, will be against the medical profession, and the courts will join hands with them in a mutual flagellation. The courts themselves have a way of avoiding such indictments unknown to us. Aside from this aspect of the case there remains to us as a profession the much more important necessity of preserving our professional dignity and inspiring confidence in our integrity and ability. The testifying of medical experts to diametrically opposite views in a given case is not a spectacle calculated to enhance the prestige of the profession from any point of view, or likely to increase the confidence of a critical public in the efficiency of our art. It then remains for us to act with promptness and determination, and unite in an effort toward a change in this whole method of giving medical expert testimony.

My own belief is that this whole system should be radically changed, and the right to give medical expert testimony in any court in this State should be lodged in a non-partisan State Board, appointed by the Governor and subject to approval by the Senate. I will not presume upon your time, nor upon my legal acquisitions, to more than roughly outline what seems to me would be the most likely to meet the requirements of the situation.

This Board should act in a capacity of instructors and advisory to the courts. It should consist of a sufficient number to amply provide for all criminal trials likely to take place at any time, and should be subject to the call of the proper courts. The members of this Board should be chosen from the ranks of our most expert alienists, men ripe in experience and judgment, and having an ascertained qualification. The functions and powers of this Board to be to examine with reference to the sanity or insanity of the accused, and shall therefore be empowered to call and examine any witness they may deem necessary, be they professional or lay. They shall have access to all evidence throwing any light upon the case, and it shall also be provided that both prosecution and defence shall, by showing reasonable cause, have the privilege of appealing to the courts for the calling of additional members of the said Board to also examine the accused, where the decision by the first expert called seems inconsistent. In no case shall any physician, not a member of this Board, be allowed to testify as an expert in insanity cases other than through the Board itself, and in open court his evidence shall be restricted to his knowledge of the facts in the case. This Board should receive its remuneration from the State. If it should be urged that the creation of a special Board by the State is unwise, there seems little objection to the designation of such a Board from the ranks of qualified alienists already in the State service.

I believe that it is only through some such method of procedure that the whole system of giving medical expert testimony can be purged of its incompetency, venality, sensationalism, and confusion, and that a trained, thoroughly experienced, and efficient class of medical experts can be secured. Thereby the ends of true justice can be most nearly meted out by the courts, and the medical profession, even here, as in other branches of its work, sustain the high position it so deservedly holds as a conservator of the human weal.

Mr. President, I would suggest including in the discussion of this paper the advisability of the appointment of a committee to consider and report upon the most feasible plan for an improvement in the present method of introducing medical expert testimony in cases where insanity is made the plea for the defence.

DANNEMORA, N. Y., February, 1895.

[1] See MEDICAL RECORD, November 17, 1894.

Meat Eating in England.—In the three years, 1882 to 1884, the consumption of meat in England was 108 pounds per head; and in the three years 1891 to 1893 it was 119 per head.

Medical Education for Women in Russia.—The applications for admission to the new School of Medicine for Women, which is to be opened in St. Petersburg at the beginning of the academic year 1895–96, are already so numerous that the Russian Education Department has decided that female medical students shall be admitted to the medical faculties of all the universities of the empire.

THE TREATMENT OF SUMMER COMPLAINT, OR GASTRO-ENTERITIS CATARRHALIS ACUTA, INCLUDING CHOLERA INFANTUM IN CHILDREN.

By LOUIS FISCHER, M.D.,

INSTRUCTOR IN DISEASES OF CHILDREN AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING PHYSICIAN TO THE MESSIAH HOME FOR CHILDREN; ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE GERMAN POLYKLINIK.

THREE years ago it was my good fortune to study some typical cases of diarrhœa in a mild and aggravated form, occurring in several hundred children, in both hospital and private practice. The results of these examinations were embodied in a paper published in the *Post-Graduate Journal*, No. 10, 1892. It was found that two classes of cases presented themselves for treatment, usually during a sudden increase in temperature of the weather; so much so, that I was led to believe, with a great many others, that there is a probability that some specific micro-organism is latent until actively developed by the sudden rise of temperature. The morbid process consists in this class of cases, chiefly of 1, vomiting, and 2, diarrhœa—the vomit depending upon the nature and the frequency of the food and the general predisposition and vitality of the patient affected; the diarrhœa, consisting likewise, as in the case of the vomit, of either undigested particles of food, greenish stools, which give a distinct reaction with nitric acid, showing the presence of bile in the passage, other stools containing mucus, cylindrical epithelium and round cells, and coming chiefly from the small intestines. We note that normally there is no bile in the large intestines, consequently all green stools emanate from the small intestines. When the mucus is not thoroughly mixed with the fæces, when the fæces are wrapped up in it, or mucus covers the fæces after evacuation, we conclude that the mucus comes from the colon, and we have colitis. Blood, when found in a bright color in stools, comes from the lower end of the bowels, and the rule that Boas in Berlin lays down is, "The darker the blood in stools, the higher up the morbid process must be looked for, whereas the lighter the color of the blood, the lower the region of the morbid or pathological process, hence it is safe to examine the anus for erosions and fissures of the anus, when the blood is bright." Duodenal catarrh can be diagnosticated only when it is complicated with jaundice; it never gives rise to diarrhœa alone. Tenesmus is observed only when the lower portion of the rectum is involved in the morbid process.

Predisposition to Diarrhœa.—Healthy infants have a normal tendency to loose liquid and semi-liquid evacuations from the bowels: 1. Partly from the condition of the intestinal tract. 2. Partly from the nature of normal food, *i.e.*, breast-milk. Peristaltic movements in a healthy child are very active. Young blood and lymphatic vessels are quite permeable, and the transformation of the surface cells are active and rapid. The peripheral nerves are superficial, more so than in adults, whose mucous membrane and submucous tissue have undergone thickening by both normal development and morbid processes. Besides, the action of the sphincter ani is not very powerful. Fæces are not retained in the colon and rectum, and little time is afforded for the reabsorption of the liquid or dissolved fæcal contents. The frequency of acids (sometimes normal) in the small intestine gives rise to the formation of alkaline salts with purgative properties. Free acids when found in the intestine show that, 1, the quantity of food is too large; 2, the quantity of the digestive fluid is too small, causing fermentation instead of normal digestion.

The diastatic effect of pancreatic juice is limited at an early age, and undigested material is carried off. Colostrum secreted after birth is apt to give diarrhœa. Milk containing too much fat or too many salts, as in anæmia, is liable to produce the same effect. Let us, then, consider the first etiology of these cases, and we find: 1. Food—improper quantity and quality. 2. Improper artificial feeding. Some authors, even Jacobi, say that mother's milk may cause this pathological condition. Mothers who are sick or convalescing, or subject to strong emotions, who nurse too often, who suffer from tuberculosis or syphilis, pregnant women, some who are menstruating, and all anæmic women secrete improper milk, hence they should not nurse for the time being, or until their milk is of normal quality. 3. Influence of weather on digestion, especially the excessive heat of the summer. 4. Improper disinfection of the nipples after nursing, and consequent decomposition or formation of micro organisms, which can infect the milk. 5. Improper disinfection of the nipples before nursing. 6. Naso-pharyngeal catarrh a distinct causative factor in gastric catarth, as was shown in a paper read by me in the Section of Pediatrics at the New York Academy of Medicine in June, 1891. Published in MEDICAL RECORD on June 13, 1891.

It is not my intention to elaborate on the anatomical changes during the course of this pathological condition nor to describe the well-known post-mortem changes, which are so much more completely described in our text-books and which cannot be demonstrated on paper, but rather confine myself to the treatment *intra vitam*.

Mechanical.—The treatment which has been most successful in my hands, and which is the result of personal experience, besides advice from such authorities as Professor Baginsky, of Berlin, Dr. Hugo Neumann, also of Berlin, and a great many others. If improper food is the cause of a disordered stomach, it stands to reason that the first point of the treatment should be to remove that offensive food. For that purpose we resort to mechanical treatment, consisting of washing the stomach with the ordinary normal saline solution. When a child is brought in with a history of vomiting I proceed in the following manner: I introduce a No. 10 flexible catheter, having more than one opening, by pushing it gently against the pharyngeal wall, continuing to push it down the pharynx into the œsophagus until we reach the stomach. The tube is never anointed with oil, because there is normally so much mucus present that we have nature's own lubrication. That a No. 10 tube is not too large for a child between six months and one year of age can be proven by the fact that after we attach a long rubber tube, ending in an ordinary glass irrigator, or ending in a long glass funnel, the child frequently has plenty of room to vomit the excess of water while the tube is *in situ*, so that the calibre of the tube allows ample room for nature's relief, if necessary. Having then introduced the tube, I usually allow water of the temperature of from 90° to 105° F. to gradually flow into the stomach until about one pint has entered. In using a funnel we can syphon off the contents of the stomach by lowering the funnel below the level of the stomach. Having emptied as much as we can, I raise the funnel above the child's head and again pour a pint of this normal saline solution into the stomach, and this process can be repeated until the syphoning proves the stomach fairly clean. So much for lavage.

The question, How often shall we irrigate the stomach? depends on the amount of fermentation present, on the condition of the child following this lavage, and also on the effect of the irrigation on the vomiting which existed prior to this mechanical treatment. It is, however, customary to repeat this washing either the next or two days following the first lavage. After cleansing the stomach of this offensive food, we prescribe rest, and insist on leaving the child at least two hours without giving food of any kind. I do, however, permit a small quantity of an alkaline water, either Seltzer or Vichy, Apollinaris water, or plain boiled

(sterilized) water to be given. Lime-water may also be given undiluted *ad libitum*. It has been found by a great many authors, and I perfectly agree with them, that alcoholic stimulants are decidedly harmful in some cases, whereas they are beneficial in others. I do not, however, prescribe alcohol in any form when a child is brought to me with a high temperature, in a very acute inflammatory state of the mucous membranes, and where an acute catarrhal gastric or enteric fever exists. Having then prescribed rest for the stomach, the next thing is to discontinue milk in any and every form. It is surprising to find that even in nursing babies we can frequently work wonderful changes by discontinuing the nursing for one-half a day or one day, while cleansing the alimentary tract. Where severe diarrhœa exists, I first try to locate the lesion in the intestine by examining the nature and frequency of the stools, and we invariably keep a record of the number of stools passed in twenty-four hours. Where there is a lientery, *i.e.*, stools containing indigestible particles of foods, we note that the lesion comes from the stomach. I have previously referred to the presence of blood, mucus, and bile in the stools, and it is very important to judge the nature of these stools before resorting to treatment. In all diarrhœas, however, it is advisable to irrigate the rectum and colon, by placing the child on its left side, introducing a flexible rubber tube, using plenty of oil or vaseline for lubrication, having passed the sphincter and gently pushed the tube beyond the rectum into the colon, as far up as we can. At times a little difficulty is encountered, owing to the spasmodic contraction of the muscles, of the internal and external sphincters, but if a little patience is used no difficulty will be encountered, and the tube will glide easily into the colon. The method of irrigation of the bowels is the same we use in irrigating the stomach, excepting that we do not seek to syphon off the contents of the bowel, but rather to allow a pint or a quart, sometimes even two quarts of warm normal saline solution to flush the bowel, and in this way wash away as much of the fæces and offending *débris* as exist at the time within the bowel. I have frequently resorted to flushing the bowel with cold water, but I found a much greater benefit from the use of the warm saline solution, of a temperature of about 100° F. I have also frequently washed the bowel with a solution of boracic acid, but have never seen any decided benefit caused by it. The same may be said of astringent irrigations, such as a very weak solution of nitrate of silver and also tannin. I have also injected a 1 to 10,000 solution of bichloride of mercury, and have never seen any benefit directly attributable to any of these remedies, so that I have come to use plain warm salt water and cleanse the bowel as perfectly as possible. The frequency of cleansing depends upon the improvement shown in a given case. While some cases required irrigation every day for one week, others would be so greatly improved after one rectal washing that it was not necessary to resort to it again. In all cases, however, a great deal of judgment and common-sense will do more than using every remedy or any remedy haphazard, without giving the stomach and bowel the proper rest, especially where there is a weakened state of digestion. In a great many cases I believe that my greatest benefit was derived by insisting on feeding my patients less often and with smaller quantities than heretofore.

Medication.—Having mentioned the cleansing of the stomach and bowels by nature's own remedies, using salt water, we try next to aid nature by administering internally some antiseptic that will aid in neutralizing fermentative and septic processes that we cannot reach either by mouth or rectum in the manner described. Of all the drugs that seem to exert a good effect in the course of treatment, I have tried calomel, and believe that a small dose of the same, properly administered, will act as an intestinal antiseptic. Whether it is the mercuric chloride or not, I am not prepared to say, but I do know and have seen very beneficial changes by the administration of one-half to one grain of calomel once or twice within three or four hours following the method of cleansing the stomach and bowel, as detailed. Castor-oil, in teaspoonful doses, I believe to be a very valuable remedy, especially so because it has a tendency to constipate after it has had its eliminative effect. Bismuth is the sovereign remedy. While I have used bismuth in the form of subnitrate, salicylate, and subcarbonate, I give great preference to the continued use of the bismuth-betanaphthol. Formerly I was in the habit of prescribing naphthol with bismuth, but since the introduction of the bismuth-betanaphthol, we have a substance which, in my opinion, is the most valuable remedy that can be given to children. This latter drug has been physiologically examined at the Imperial Institute for Experimental Medicine at St. Petersburg. According to Professor Von Nencki, betanaphthol-bismuth agreed well with patients even after long-continued use. This remedy is the outcome of a great many other non-toxic products from the laboratory of Dr. F. Von Heyden, and is indicated in all forms of bacillary diarrhœa, in choleraic diarrhœa, especially, however, in those forms of acute catarrhal gastro-enteritis, as we are in the habit of seeing them in our city to-day. The naphthol combined with bismuth not only has an antiseptic effect within the intestines, but also has the astringent property of the bismuth. Vomiting never followed the administration of the drug, nor was any other symptom directly attributable to the drug which would contra-indicate its use.

Only recently a child, nine years of age, suffering from a most severe form of typhoid fever with very offensive green stools, seemed to improve very much during the course of treatment with this drug. The betanaphthol-bismuth seems to exert some influence on the offensive smell usually to be found in these typhoid and bacillary diarrhœas.

While it is not proper for me to enter into the physiological action of betanaphthol-bismuth, I entirely agree with Professor Hueppe,[1] who lauds this new remedy as a most powerful intestinal antiseptic, and recommends it as a specific in cholera. Von Nencki claims that this drug was well borne by patients and continued for a long time. He further claims that the drug, when introduced into the stomach, is partly decomposed into naphthol and bismuth. A large part of it, however, passes into the intestine, where the acid reaction and the presence of the pancreatic juice complete the disassociation. Naphtol is but partly eliminated with the urine; the residue passes through the whole alimentary canal, and is finally excreted with the fæces. The bismuth in the human subject is entirely excreted as the sulphide with the fæces; in the dog a large part becomes the soluble chloride, on account of the relatively much greater formation of muriatic acid in that quadruped. In no single case were any toxic symptoms observed, though daily doses of from seventy-five to one hundred and fifty grains were given. In our country Wilcox, in a paper, "The Preparations of Bismuth," read before the New York Clinical Society, December 15, 1894, speaks very highly of the betanaphthol, especially so in all fermentative bowel complaints. Dr. Hugo Engel, of Philadelphia, in the *New York Medical Journal*, March 30, 1895, in a paper entitled "The Therapeutic Effects of Betanaphthol-bismuth," also speaks very highly of the value of this drug. He says, in speaking of the betanaphthol-bismuth: "I have found it so reliable and so superior in intestinal complaints to all the various bismuth salts previously known, that I have determined to publish my observations for the benefit of the profession and suffering humanity."

While the use of the phenols for internal medication seems to have been limited, it can only be explained

[1] Berliner klinische Wochenschrift, 1893, No. 7.

on the ground that they are very poisonous in their free state. Their causticity makes them injurious to the gastro-intestinal mucous membrane, besides they have a very disagreeable odor and are repugnant to the taste, but in combination with bismuth the noxious properties of the phenols appear to be neutralized. Then when these substances are introduced into the system they are decomposed, the phenols being liberated exert a characteristic antiseptic effect, while the bismuth oxide that is set free combines with and fixes the toxic albumins in the intestines.

A child, one year old, can be given five grains betanaphthol-bismuth every two, three, or four hours, as required; a child half a year old one-half the dose. I always insist on giving these powders with a little boiled (sterilized) water, and preferably when the stomach is quite free from food. If there is a great tendency to vomiting and the child does vomit the first or second dose given, it is my custom to immediately follow the vomit by administering another dose of the same quantity. I believe the fear of giving opium is exaggerated. It is one of the most indispensable drugs in the treatment of diarrhœa with pain that we have today. Great care must be exercised, however, to give only the required dose. I have, therefore, frequently combined Dover's powder with the bismuth phenol, sometimes giving one-tenth to one-third of a grain of Dover's powder with each dose of the bismuth; also I have had very good results from the administration of nitrate of silver, one-fiftieth to one-thirtieth of a grain, or even more, every few hours, where bleedings from dysenteric stools have existed. I do not refer to bleeding caused by the small erosions or from the ordinary tenesmus caused by fissuræ ani, which can be controlled much easier by local treatment than by administering drugs per os. It is wise, therefore, to carefully examine the anus in all these cases, where children appear to suffer very much pain from these erosions. The painting of the anus with a six per cent. solution of cocaine or the watery solution of opium will give great relief.

The antipyretic treatment of these gastro-intestinal catarrhs is one that requires great judgment. For example, we frequently have, as in acute gastritis, a sudden elevation of temperature to 105°, 106°, or even 107° F., and this hyperpyrexia can be best controlled by the administration of a bath in the following manner: We place the child in a blanket and introduce the whole body up to the neck and shoulders into water, at a temperature of 90° F. I gradually add cold water to lower the temperature of the water until it reaches 70° F. In summer, where ice is handy, I place the child into warm water and add a large piece of ice to this warm water, and in this manner allow the temperature of the water to be gradually cooled, until the bath thermometer shows a temperature of about 70°. The duration of the bath should not be more than five minutes, otherwise it will be followed by a chill which is sometimes prolonged. The frequency of the administration of these antipyretic measures depends on the condition of the child. I have frequently found that the temperature of 105° or 106° F. can be reduced by one bath three and four degrees during the bath, and that the temperature of the body still sinks one and even more than one degree after the patient is taken out of the water. The antipyretic effect of these baths will last at times two and three hours, and if the temperature again rises we can administer a bath every few hours, as we see fit. It is hard to generalize the treatment of summer complaint, because we have to individualize in most of our cases, and find that certain active measures are very well borne by one class of cases which are not at all tolerated by others. One point is important, and that is to reduce the very high temperatures that occur in the course of summer complaint, owing to the great risk that we run from continued elevation of temperature in causing convulsions and possibly death. In the management of cholera infantum I am in the habit of placing the child with a very high temperature at once into the bath as above described to reduce the elevation of the temperature as much as possible. The next step is to cleanse the stomach and bowels by irrigation as above described, so as to free the stomach from all fermentative products and render it as completely sterile from poisonous bacteria as possible, and by all means to put an ice-bag on the top of the head. While we know that sun-stroke in the adult is usually most dangerous and fatal in alcoholic subjects, we do not know how much good or harm is done by the administration of alcohol in the course of a severe cholera infantum. A large experience of these severe cases as we see them in this city, where a child is brought in in a condition of collapse, with cold extremities, covered with large beads of cold perspiration; the eyes half open, the pupils dilated, the head very hot, the fontanelle widely open, usually depressed, with rapid pulsation; liquid, watery, sometimes greenish, sometimes brownish stools, more often accompanied by vomiting; a tongue that is brown or red, studded with white spots, dry, more often protruding from the mouth; the eyes sunken, surrounded by deep black rings; little or no urine voided; the abdomen at times very tympanitic, at other times retracted; a distinct typhoid appearance, while the body has a cadaverous smell—where we have a clinical picture of extreme exhaustion, as above described, the pulse feeble, at times intermitting, in some cases 180 per minute, in others possibly 60 pulsations, and where we are in the midst of an extremely hot summer's day with the temperature of the air between 95° and 100° F. in the shade, the first duty is to cool the surroundings as much as possible. It is in these cases that so much good can be accomplished by a sudden change of air from the city to the sea on excursions, such as, for example, are given with such wonderful benefit by the St. John's Guild and other sanitariums. The well-known constipating effect of the sea air on adults is here, I believe, beneficially shown and proven by the fact that at times two hundred or three hundred children that have suffered from a continuous diarrhœa lasting a few days or more will by one small sea-voyage, lasting one day in these trips, suddenly have the diarrhœa stopped, which will continue to remain so until the next sudden approach of hot weather.

Stimulation.—The strongest nerve stimulant is musk. In urgent cases I have given 1 to 2 grains within half an hour in a little mucilage of gum Arabic until 6 grains have been given. Camphor, ¼ to 2 grains, can be rubbed up with glycerine; or 10 to 15 drops of spirits of camphor in some cases seem to do good; in obstinate cases, however, hypodermic injections of spirits of camphor prove serviceable. While it is very rare to use alcohol in any or all forms of gastro-intestinal catarrh, I have, however, injected in collapse a teaspoonful of alcohol in a pint of hot water through a flexible catheter (No. 12) into the bowels, or given a few drops of whiskey in rice gruel or barley gruel. A word more about calomel. A great many children vomit after the administration of calomel, so that it is wise not to overlook this point, but it does augment the flow of bile by stimulating the bile-ducts and hence it is a very valuable remedy. The tannate of quinine, which has been so highly recommended, I have used in our dispensaries for the last six or seven years, and have invariably resorted to other drugs; it is therefore a very poor drug to be used in this condition.

Diet.—Our next step will be to nourish our patient. If our patient is a nursling we must carefully inquire into the quality and quantity of its mother's or wet-nurse's milk. The microscopic examination of the milk will be necessary, besides the creamometer, which is recommended by Holt, can be used to estimate the quantity of fat and cream in the milk. It is wise to in-

quire into the conditions previously mentioned in this paper—*e.g.*, tuberculosis, pregnancy—when the lactation is interfered with, and if we find such conditions existing, then we must resort to hand-feeding—properly sterilized milk, diluted according to the age of the child. If the child is hand-fed it is a cardinal rule in all cases of summer complaint with vomiting and diarrhœa to discontinue milk and to give the child barley-gruel, or what I have found equally good, rice-gruel. If the child does well it is a good plan to change the food from time to time, and to give one day corn-starch or rice and the next day barley. The white of an egg or the yolk of an egg beaten up with sterilized water can also be given advantageously during the course of a diarrhœa; so also have I found some good by the administration of beef blood, made by broiling fresh steak and expressing the juice with a lemon-squeezer, and administering twenty-five or thirty drops at a time to a child of six months or over, two or three times a day. If vomiting is very persistent and the stomach has been thoroughly cleansed and cannot be controlled by the measures resorted to above, I frequently discontinue all feeding per mouth for twenty-four hours, giving the stomach absolute rest, and then resort to

Rectal Alimentation.—For this purpose I use peptonized milk (thoroughly peptonized) or the yolk of egg with starch-water, or beef blood as described above, with starch-water, or barley-gruel, using between two and four ounces for one enema. This quantity I inject into the rectum very slowly every two, three, or four hours. It is always necessary in rectal alimentation to thoroughly wash the lower bowel by using an enema of soap-water or glycerin and water before each feeding.

Hygienic.—Having attended, then, to the mechanical treatment, medication, and looked after the proper diet of our case, we next try to give our patient as much cool air as possible. I have previously referred to the importance of taking a child away from atmospheric influences, which most likely cause this pathological condition, and where this is not possible, I remove the child into the largest and coolest room of the house. Where sea-air is not obtainable, it is wise to add some sea-salt to our water in administering the baths previously mentioned, as they have a very invigorating effect. Occasional sponging with equal parts of alcohol and water or a small quantity of Florida-water brightens the children and seems to check perspiration. Children in this condition should be bathed daily, and where extreme prostration exists, they can be bathed twice daily with salt water, followed by rest and placing a small rubber bag half filled with cracked ice over the top of the head or immediately over the pulsating fontanelle and left *in situ* for a number of hours. In other cases where there are symptoms of cyanosis with cold extremities and great perspiration, with pallor of the skin, a hot mustard bath is indicated—about a handful of pulvis sinapis nigræ wrapped in some linen and suspended in water of about 100° F. Immerse the child's body and gradually raise the temperature of the bath by adding boiling water until reaction sets in; then wrap the child in warm blankets. In extreme stupor I have sometimes given to advantage a few drops of the aromatic spirits of ammonia with a little boiled water, especially where the pulsations were very feeble.

To sum up, my plan of treatment for a given case of catarrh of the gastro-intestinal mucous membrane, resulting from the combined effects of extreme heat and improper feeding, would be: 1. To irrigate the stomach as previously detailed, to free the gastric mucous membrane as much as possible from offending decomposing food and consequent fermentation. 2. To free the bowel in the same manner from all offending fæces possible by irrigating with lukewarm water and flushing the colon and rectum till the contents flow away clear. 3. Never resort to antipyretics, as antipyrin and quinine or other similar drugs, in reducing the temperature, but invariably resort to hydropathic measures, relying on the warm bath, gradually cooled from 90° to 70°. Duration of bath in all five minutes, to be repeated every few hours if necessary. 4. Placing an ice-bag on the top of the head, following the bath, and placing the patient in the coolest possible room, if we cannot have the child immediately removed to cool sea-air. 5. Unless it be a nursling, I invariably proscribe milk; and if a nursling then discontinue the breast at least one-half day to give the stomach absolute rest. 6. I administer beta-naphtol-bismuth in doses of five to ten grains to a child of one year every two, three, or four hours, depending on the nature of the case. 7. If vomiting persists and cannot be controlled by medication, I resort to rectal feeding, and administer the bismuth in a small suppository, also per rectum, but invariably doubling the dose required per mouth. 8. I invariably warn against the danger of administering alcohol, and any wine or beer. I administer alcohol, if at all required, myself, per rectum, as detailed above. 9. Cold sponging to check the perspiration with equal parts of alcohol or water or using bay rum is very refreshing and grateful, besides doing service in cooling the body. 10. Where cyanosis and very cold extremities exist, we have to individualize our treatment and sometimes resort to hot mustard baths, in preference to previous hygienic measures detailed.

It is important to remark that the cause of all or nearly all gastro-intestinal disorders originates in the stomach by and through not only the food given, but an improper assimilation of the same, due no doubt to atmospheric surroundings, and hence a complete breaking off and stopping of feeding per mouth is very beneficial to a great many cases, and where, therefore, we have extreme vomiting, which cannot be controlled by other means, the importance of rectal feeding and absolute rest of the stomach cannot be overlooked.

187 Second Avenue.

A CASE OF EXOPHTHALMIC GOITRE, WITH MONOCULAR SYMPTOMS AND UNILATERAL THYROID HYPERTROPHY.[1]

By PERCY FRIDENBERG, M.D.,

ASSISTANT SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; OPHTHALMIC SURGEON TO THE FRENCH HOSPITAL, NEW YORK.

Since Graves's classical observations first drew attention to the symptomatic combination of thyroid hypertrophy, cardiac palpitation, and "Anæmic Protrusion of the Eyeballs," and Basedow, independently, and but a few years later, described similar symptoms as characteristic features of a distinct "Exophthalmic Disease" (Glotzaugen-Cachexie) no completely satisfactory theory has been advanced in explanation of the pathology and etiology of the interesting affection, which as Graves's or Basedow's disease, represents a very definite and not uncommon clinical entity.

In view of the present state of our knowledge on this subject the report of a case of exophthalmic goitre, with the unusual features of limitation of ocular symptoms to one side, and unilateral enlargement of the opposite lobe of the thyroid gland, may not be without interest.

The patient in whom this rare variation was observed applied for treatment on November 3, 1894, at the New York Eye and Ear Infirmary, and was referred to me for an examination of the refraction by Dr. Gruening, to whom I am indebted for permission to report the following notes: The patient, Mrs. A. J——, is twenty-four years of age. Her father and mother are living, and in perfect health, aged respectively fifty-four and forty-eight years of age. Six sisters and four brothers,

[1] Read before the Section on Ophthalmology of the New York Academy.

all robust and well, are subject, according to the testimony of the patient, to nervous excitement. The patient herself has always been well, but since childhood she has been nervous and easily frightened. She has been married four years. Three years ago she aborted at the fourth month, and has not been pregnant since. From the time of her marriage she has been almost constantly worried and excited by domestic infelicity, and about six months ago her condition was aggravated by a particularly unpleasant occurrence, the precise nature of which I did not investigate. Within a few weeks the patient noticed that she became fatigued on the slightest exertion, particularly after walking or climbing stairs, flushing frequently and perspiring freely. Her nervous excitability increased markedly, with the additional symptom of palpitation and dyspnœa, and occasionally the sensation of throbbing in the vessels of the neck.

The patient, who is a dressmaker, found that her eyes ached and that vision became blurred after sewing a few minutes, and she was told that "she looked strange," and that "one eye was larger than the other."

My attention was immediately attracted by the peculiar expression of the left side of the patient's face, due principally to the staring appearance of the eye. It was this characteristic feature which at once suggested a diagnosis. The palpebral fissure on this side was widened by a marked retraction of the upper lid, which allowed almost two millimetres of the sclera to appear above the margin of the cornea when the visual axis was horizontal. The globe was distinctly prominent, but not to a high degree, and Graefe's symptom was readily elicited. The condition is well shown in Fig. 1, taken about three weeks later. Involuntary winking was decidedly infrequent, but not evidently impaired. The vision was normal in both eyes; the refraction emmetropic. There was an insufficiency of the internal recti of 2° and 5° respectively for distance and near vision. Ophthalmoscopic examination showed venous pulsation on the disc in the left eye, but arterial pulsation could not be detected. The right eye showed no abnormality; the appearance of this side of the face was perfectly natural. There was some flushing of the face, more marked on the left side, and greatly increased by even slight mental excitement. The thyroid was not noticeably enlarged, but on palpation an increase in size of the right lobe, and of the isthmus was made out. There was a fine tremor of the tongue and hands, almost fibrillary in character, and much like that observed in paralysis agitans, but somewhat slower (5 to 6 to the second). The heart was over-acting and tumultuous, at times intermitting; the second pulmonic sound accentuated. There was no evidence of a valvular lesion, but the area of cardiac dulness was increased to the left, and the apex-beat was heaving and diffused over the precordia. There was marked capillary pulsation on the breast and neck. A loud venous hum was heard over the jugular vein, and a blowing murmur, coincident with the first sound of the heart, over the enlarged right lobe of the thyroid. The lungs were normal, but inspiration was superficial, and at times, gasping; the thorax appeared somewhat flat. There was marked pulsation of the carotids, especially on the left side, but the radial pulse was quite small and compressible, averaging 120 to the minute when the patient was at rest. Although I impressed upon the patient the importance of avoiding all exertion, physical and mental, some weeks elapsed before she realized the necessity of systematic treatment. I advised rest in bed or on a lounge for several hours in the morning and afternoon, general regulation of diet, and the use of ice-bags over the heart and neck for excessive palpitation. Tincture of digitalis in doses of five minims three times a day was prescribed, with a tonic containing iron, strychnine, and quinine. The heart-action was not improved by the digitalis, which after several weeks had been increased to ten minims four times a day, and, although the ice-bags promptly relieved the palpitation, the patient found it inconvenient to use them regularly. The digitalis was discontinued, and tincture of strophanthus, three minims, three times a day, was ordered, with fifteen grains of sodium bromide on retiring at night.

This case has been under observation for six months, and the condition at present is slightly improved. The heart-action is somewhat less rapid, the palpitation, subjectively, much diminished. The exophthalmos is still present, although not in the same degree as before, and the retraction of the upper lid is hardly noticeable.

The improvement in the patient's expression has been noticed by her friends, and this has had a beneficial effect on her general condition. The prospect of ultimate complete recovery seems good.

In the above case all the classical symptoms of Graves's disease were present, together with a number which, though not of prime importance, are characteristic of the affection. Of these I may mention the tremor (Marie), restlessness and nervous excitement

Fig. 1.

(Charcot), insufficiently of the interni (Möbius), superficial respiration (Bryson), and the flushing and hyperhidrosis with the attending diminution in resistance to the galvanic current. The most striking feature of the case, however, is undoubtedly the peculiar limitation of the ocular symptoms to the left side, combined with a "crossed" hypertrophy of the right lobe of the thyroid. Unilateral symptoms in Graves's disease are so inexplicable by the ordinary theories that some writers on the subject[1] have denied the possibility of such a variation, while Berger[2] considers the presence of unilateral exophthalmos sufficient evidence to exclude a diagnosis of this affection. There is no doubt that many of the cases published as Basedow's or Graves's disease, especially those dating from the earlier years in the study of this disease, were based on insufficient observation. Affections of the cervical sympathetic with atypical symptoms,[3] complicated cardiac lesions,[4]

hysterical manifestations in chlorotic girls, and, in a number of cases, true endemic or sporadic goitre with pressure symptoms on one side,[1] were all thrown into the convenient category of morbus Gravesii. A large number of the cases compiled by Hirschberg[2] in his historical and critical essay are found on reference to the original articles to be ordinary bilateral cases;[3] in others there was a difference, more or less marked, in the degree of protrusion of the two eyes,[4] while in a third series there was only temporary limitation of symptoms to one side, the exophthalmos appearing somewhat later in one eye than in the other.[5] Excluding the doubtful cases, I find the following references to the condition under discussion:

Demours,[6] observed in a young girl, eleven years of age, a prominence of the left eye of one and a half lines, which had persisted for three years. The patient had had slight thyroid enlargement since birth. Her mother showed a disposition to thyroid enlargement since childhood, and after her first confinement developed a goitre, which steadily increased in size.

Desmarres,[7] reported, under the title "De l'Exophthalmie produit par l'hypertrophie du tissu cellulo-adipeux de l'orbite," several cases of Graves's disease, in one of which he observed unilateral exophthalmos of a slight degree in the right eye of a young woman, aged thirty, who suffered from nervousness, palpitation, and thyroid hypertrophy. There was retraction of the upper lid; the sight was perfect and motility normal. After treatment for three months with potassium iodide internally and unguentum iodi applied locally, the condition improved noticeably. In his general remarks on this subject Desmarres draws a graphic picture of the physiognomy in this affection, and in particular calls attention to a symptom which Stellwag is supposed to have discovered sixteen years after Desmarres described it in the following words:

"Lorsqu'on regarde attentivement un malade atteint de cette affection, on remarque, comme premier symptome, que la paupière supérieure ne s'abaisse plus comme dans l'état physiologique sur la partie supérieure de la cornée, lorsque l'œil regarde horizontalement; au contraire, la cornée reste découverte en totalité, ce qui donne à la physionomie quelque chose de hagard fort désagréable à voir. A un degré un peu plus avancé encore, le malade a les yeux d'un homme en fureur, et celà établit un contrast choquant avec la tranquillité du reste de la physionomie." The rest of this interesting monograph is devoted to the differential diagnosis of the exophthalmos in Graves's disease from that due to hydrophthalmos (bouphthalmos), orbital cellulitis or emphysèma, distention of the sinuses, orbital tumors, and other causes.

Mackenzie[8] saw one case. His patient, a delicate, anæmic young woman, whose sister had been under treatment for years for Graves's disease, suffered from amenorrhœa with nervous symptoms, dyspepsia, and constipation. After several months of mental worry and severe physical exertion during the summer, the right eye began to protrude, and the thyroid became enlarged. The symptoms were much improved by the administration of the tincture of iodine (dose not stated), with local application of iodide of potassium ointment to the neck and temporal region.

Präel[9] noted the development of right exophthalmos with bilateral thyroid hypertrophy during convalescence from acute bronchitis of a man, aged fifty, who suffered from palpitation and other signs of cardiac disease since his twentieth year. After a long time the left eye also became prominent. The case terminated fatally, and the post mortem examination revealed extensive atheromatous changes in the aorta, with evidence of mitral stenosis and insufficiency. In two other cases right exophthalmos was observed in young girls, nineteen and fifteen years old, respectively, who were chlorotic. In one case palpitation and hyperhidrosis appeared later and persisted for several years. In the other case a severe emotional disturbance was the determining cause. The exophthalmos suddenly became much more marked about five years later after a severe attack of hæmatemesis and brought about a condition of acute anæmia. Struma now appeared for the first time.

Chvostek[1] reports the case of a woman, aged fifty-five. Her mother had shown marked symptoms of nervous weakness since youth. Her father had had a valvular lesion, and a sister had been affected with Graves' disease for twenty-five years. The patient had passed through severe mental excitement eight years before, and soon after presented symptoms of exophthalmic goitre with striking unilateral symptoms. The right eye was noticeably prominent, the right lobe of the thyroid much enlarged. Hyperhidrosis, flushing, and emaciation, all limited to the right side, appeared later, and the general condition became very bad, although the patient eventually recovered completely.

A most remarkable case is reported by Burney Yeo.[2] The patient, a woman, aged thirty-five, had always enjoyed good health, although extremely nervous, until her fourth confinement. Symptoms of puerperal sepsis then set in which lasted for three weeks. When she got well the patient's friends would not let her look at herself in the glass because she "looked so wild." There was marked exophthalmos on the left side, but it was difficult to say whether the right eye was, or was not, at that time, more prominent than natural. The right lobe of the thyroid was considerably enlarged, but there was little increase, if any, in the size of the left lobe. At about the same time the eyelashes and the hair of the eyebrow on the left side began to fall out. The general symptoms of nervousness, flushing, hyperhidrosis, and palpitation, with a pulse of 136, were noted. Both the goitre and the exophthalmos were markedly unilateral, but on opposite sides. After nearly six months the right eye began to protrude, and the falling out of the eyelashes and of the hair of the eyebrow on the corresponding side was noticed. At the same time the opposite lobe of the thyroid, which had formerly appeared to be normal, began to enlarge, and soon equalled the right lobe in size. Yeo cites a second case of right unilateral exophthalmos which had persisted for one year in a robust and healthy young girl of twenty-three. Palpitation and nervous symptoms developed, the pulse ranging from 116 to 140, but there was no goitre.

Becker[3] reports the case of a lady, aged twenty-eight, who had been married seven years and was the mother of a strong, healthy boy. A second pregnancy had not occurred, as dysmenorrhœa with nervous symptoms had followed the first confinement, and had eventually developed into hysteria. Since one year occasional protrusion of the left eye had been noticed, while the right appeared perfectly normal. Palpitation was complained of at times, and there was slight enlargement of the thyroid. On examination the sight was found to be perfect. There was only slight exophthalmos with pulsation of the retinal arteries in the left eye. There was no prominence or other morbid symptom in the right eye.

Abadie[4] describes the following case: A young woman, aged twenty-eight, who had been troubled for

several months with excessive feebleness, general malaise, palpitation, and marked nervousness, had been under treatment, without relief, for anæmia, a diagnosis having been made "by exclusion," as physical examination had failed to reveal any organic evidence of disease. Some time later the patient noticed a greater prominence than usual of the right eye. The characteristic expression of the eye, due to retraction of the upper lid, immediately drew attention to the real nature of the case. The pulse when the patient rested was 96. The prominence of the right eye was manifest. There was a slight enlargement of the thyroid, affecting the isthmus only. The left eye appeared perfectly normal. In the case of a man, aged thirty-four, who had suffered with palpitation for three years, Maher[1] found enlargement of the thyroid, notably on the right side, and exophthalmos of the right eye, the cornea being two and a half to three millimetres in advance of the left. This condition had been noticed by the patient for one year. Graefe's symptom was not present.

Fig. 2.

In this country no case of unilateral exophthalmic goitre has been published, and, to my knowledge, but one has been observed. I am indebted to Dr. George W. Jacoby, of this city, who presented the case at the Monthly Scientific Meeting of German Physicians, in December, 1893, for the following details, and the accompanying photograph (Fig. 2):

Kate P——, thirty-three years of age, has complained for about two months of general nervousness, palpitation, and sweating. For about the same length of time she has noticed a peculiar expression of the right eye and slight prominence. On examination, Graefe's symptom, with retraction of the upper lid and slight exophthalmos, all on the right side, were noted. The thyroid seemed to be somewhat enlarged; the right lobe distinctly fuller than the left. Möbius's symptom was distinct, but there was no loss of involuntary winking. The right cornea was perhaps slightly anæsthetic. In addition to these symptoms, there was tremor, and a bronze decoloration of the skin.

[1] Lancet, 1886, No. 1, p. 1221.

In all but three of the thirteen cases reported the right eye was affected. Of the three cases involving the left eye, but one, that of Burney Yeo, was associated with hypertrophy of the contra-lateral lobe of the thyroid, and in this case both lobes eventually became much enlarged. Ocular and thyroid symptoms limited to the right side, were seen in Chvostek's case only. In my case there has been, so far, no evidence of an extension of the affection to the right side, and the general improvement in the patient's condition leads me to believe that the present "crossed" condition will eventually recede without any change in the peculiar limitation of the symptoms.

60 West Seventy-sixth Street.

WHERE SHALL OUR CONSUMPTIVE PATIENTS BE SENT? SOME PRACTICAL POINTS FROM THE WRITER'S OWN EXPERIENCE.

By WILLIAM B. BERRY, M.D.,

Pasadena, Cal.

Let me express to my friends of the Orange Mountain Medical Society my cordial and undiminished regard. Your society held and still holds many of my best professional friends, and it is this reason which leads me to present to you some of the results of seven years of observation of phthisis in different climatic resorts in this country. These years have made vacant several places in your ranks—vacancies I do not like to contemplate. The dreary distance that separates us is kind for once, and it helps me to-night to picture all the chairs filled as they were in the old days. Once when I lived among you I was called to supersede one of your honored members, who was impeached by paterfamilias as being "too scientific." It is with mingled feelings that I recall the perfect satisfaction with which my ministrations were accepted by that household through many years. Though the quality which this infers is not the one to plead before you, I beg you to lend your ears and listen.

The writer's problem has been, as you know, to regain his health and have a home the year round in a civilized community, under his own flag. This is not presented as a dissertation on "climate" or on its factors and their method of action, and I shall purposely avoid figures and statistics. Often an accurate estimate of the properties of an air may be made by avoiding for a time our instruments and gauging it by the amount of comfort it brings. There *are* good climates and health resorts, so called, in this country; there are *so many* that no one of them can properly assume airs of exclusiveness. Able, honest, painstaking men have put these places on record, but the profession has been bothered into scepticism by the genius who "writes up" climate from the car window, by the man who directly or indirectly has it for sale, by the sick pessimist who has failed in his search for health, or by the healthy pessimist who has failed in speculation. A hunt for a perfect climate is a rainbow chase. Probably there is no spot where at times one could not reasonably and easily imagine himself on the streets of Orange and Montclair—in nasty weather too.

Your correspondent will speak briefly of Colorado, where a year and a half was passed; of Asheville and its vicinity, where more than a year was spent, and of Southern California, where in various places he has resided for three and a half years. To the average busy doctor a health resort presents itself as an unfamiliar medicine, and he straightway and with suspicion questions: What is it? How does it taste? What is it good for?

Colorado is a type of a land of high, dry air, sunshine, and arid soil. That elevation and atmospheric dryness have a decided influence on pulmonary con-

sumption goes for the saying. It is safe to assert that a great majority of non-laryngeal, and a respectable minority of cases with laryngeal, complications should have the driest air comfortably attainable. This notwithstanding the fact that a few of these cases do well on the coast or at sea, or even in a damp valley. As for altitude, the writer is each year firmer in his convictions that it is the most powerful climatic (or other) therapeutic agent we have for the arrest and cure of this disease, but it is a two-edged sword. It is, in ignorant hands, a most dangerous remedy, and even the wisest do not always know just where or how much to give, but this we can as truly say of atropia or digitalis. Whether an altitude of three thousand or four thousand feet gives all the good results and has none of the evils of one of six thousand or eight thousand feet is a question for further observation; but I should be inclined to say "No" decidedly. The value of the climate of the Rocky Mountain region is beyond question, and one has but to look about in every town to see those who came there very ill leading active, efficient lives.

In Colorado, as in every other resort, a dreary picture may be drawn, if only the disagreeable features are spoken of, but they should be noticed and weighed or disappointment and harm may occur. If the climate-seeker expects to find a spot where he does not have to use vigilant wit against the vagaries of nature, he had better stay at home. Among the peculiarities, to use no harsher term, of Colorado climate, should be noted a great difference between day and night temperature, as exists, I believe, in all high altitudes, and also holds in Southern California.

Again, as elsewhere, dryness means dust, if there is any soil and air motion, and an exaggerated air motion seems to be inseparable from all health resorts worthy the name. A certain amount of wind is wholesome, no doubt, but Colorado may truly be said to have more than is necessary or pleasant. Dr. Fisk, of Denver, and Dr. Solly, of Colorado Springs, have made analyses of the cases of phthisis coming under their care during a term of years, and show improvement in sixty-six and two-thirds per cent. Their deductions are beyond question fair accurate, and true; still it would be safe to say that of the indiscriminate throng of consumptives who press out to that country, far more are injured or receive no benefit than are in any way helped. For this two comprehensive reasons may be given: 1, So many unsuitable cases are sent; 2, so many do not at once put themselves under competent local medical care.

We must all recognize the fact that the most skilful advice cannot be always right in its choice of a climate, and that in each instance there is a large amount of experiment. Again, we must remember that a large percentage of these cases sooner or later reach a fatal termination, go where they will and do what they will. It is not an infrequent thing in an altitude such as Colorado Springs (six thousand feet) to see developed a train of nervous disorders demanding a retreat to a lower level. It would seem to be true in a measure, though not to the extent formerly supposed, that a "cure" wrought in a high altitude puts the subject in prison, and that he does not have the wider range of choice of one who regains his health within a short distance of the sea-level. Practically the difference is not great, for good sense requires that anyone "recovering" from phthisis should strive to remain in a climate as nearly as possible identical with the one in which the cure is wrought.

The Asheville region is one of great beauty, and presents the advantages of a varying moderate altitude. In a climatic way it is a decided improvement on the Atlantic coast. Its proximity to the Eastern centres and the comfortable character of a great part of the year make it a desirable resort for those who do not need, or cannot reach, or should not attempt, the more decided change that begins only at the eastern edge of the Rocky Mountain plateau. I cannot speak of any of the other places in the South, for I have no direct acquaintance with them, but their name is legion.

Southern California.—It is difficult to give a fair impression of a climate from a written page. The feat has never been accomplished. It bears the same relation to the real thing that a cook-book does to a dinner. To me, all things considered, Southern California seems to present more of the essentials of health and comfort for a larger proportion of invalids than any other section I have visited. One finds that as a class those who have knocked about the most are the best satisfied here. No one who has not lived in the country the year round and leisurely visited the various places can have any just idea of it. It should always be remembered that it is a land of many and varied climates, of wide range of heat and cold, dryness and moisture, of mountain height, sea-level, and below the sea. Going a score of miles from its principal town, one is at the sea; an equal distance in another direction, six thousand feet above it. Journeying three or four hours from the ocean through ever increasing dryness brings one to the great dryness of the desert, at, above, or below the sea-level.

At first the great stretches of bleak treeless shorn desolation are a surprise, if not a shock, to those who are acquainted only with the lavish hand of nature through the Eastern summers. Here, through most of the year, nature wears colors not in vogue in the East, and it often takes a little time to get used to her strange gowns, but we soon learn that her taste is unerring. The winter rains make the land green for a short time, then it lapses into its normal browns and gray-greens for many months, save where a discouraged stream crawls, or where the hand of man leads water to orchard, garden, or lawn. If one may speak in general terms of a vast area in which there are varying conditions, there may be said to be throughout Southern California a warm midday and a cold night half the year, a hot midday and a cool night the other half. With the hot sun, a cool breeze from the sea, save in the early fall, when it dies down. The hot weather is the dry weather, and comfortable if one can order his employment. In most locations there are a dozen days a year of dry, parching, disagreeable wind from the desert. During the winter and early spring many rainy days and then dry skies for many months. Dry, warm weather means dust and flies, and they are here, but are to be conquered in the usual way. For three months in the late spring and early summer, and as an occasional thing at any time in the year, there is fog, which a buoyant optimism calls "dry" though dripping at every pore. This fog increases as you approach the sea and go up the coast. The country in the interior, away from the cooling influence of the sea, may be depressingly hot in summer and autumn. The immediate seashore is always cool, and the nights are relatively warmer than in inland places.

The only difficulty is in finding, for those who cannot stand the sea nor an altitude of at least five thousand feet, a convenient place to retreat from the heat of September and October, and perhaps that of August and November. There are some phases of consumption that do well on the shore, but it should be understood that to the vast majority of pulmonary invalids the Southern California ocean-side is not friendly. The islands, a score or more of miles out in the sea, offer a satisfactory refuge from the heat for some who cannot brave the air of the main coast. Perhaps the cultivation and irrigation of the soil is in certain locations a disadvantage to the sensitive throat. If it is, it certainly cuts very little figure and may be easily avoided. The most wholesome air the sick one breathes is no doubt amid absolute isolation and desolation, but those of us who have experimented are willing to compromise the matter and take a cook and some cultivation in "ours."

As far as I can learn, the high mountain resorts in

Southern California are crude, and if a permanent residence at five thousand feet or over is contemplated, the "resorts" in the Rocky Mountain region offer better advantages.

If our cases of phthisis are to seek relief by change of climate, where shall they go? Were one to make a round of visits in any one of our distant climatic resorts, he would be convinced that a large proportion of the invalids should have remained at home. Do not let me be understood as deprecating the climatic treatment of phthisis. It stands first of all curative and palliative agents, but taking for granted that the doctor knows something about the different locations, there are two great preliminaries to be studied before advice to go any distance is given.

1. The Patient's Environment in all Its Features.—His bank account, his habits, his friends are by no means the least important items. Frequently it is as essential to know the nerve and quality of a man's wife as to examine his sputum, if he is to fight for health in a strange land. To send anyone away from a good home to be grudgingly and with suspicion taken into a boarding-house, there to lie, ill and homesick, receiving in exchange for what he has resigned a little drier air and a little more sunshine, is to place a very considerable balance on the wrong side of the ledger. This what is every day happening in these places.

2. The Physical Condition of the Patient.—I have attempted to classify the common forms of phthisis pulmonalis and to make a choice of climate for each: *A*, Incipient cases; *B*, those with considerable consolidation but no fever, and those with pleuritic deposits; *C*, those very sick; *D*, emphysematous cases; *E*, laryngeal cases; *F*, cases in which the fibroid process is marked.

If an apology is due for the arbitrary and unscientific construction of these divisions, it may be said they thus group themselves in the doctor's office, if not in the laboratory.

A. Incipient cases at their earliest discovery, or those without physical signs, but where from heredity or evident depreciation we suspect or fear the advent of phthisis. We may also include here the cases of slight hæmoptysis without recognizable consolidation. Often the early diagnosis is very difficult, if not impossible, for the disease may exist before the chest signs appear, to say nothing of these signs being present before we discover them. No doubt some of us can bring to mind instances where the symptoms of fever pallor and emaciation were not understood until cough or even hæmoptysis supervened. Very rarely, however, does the disease come without more or less cough, and if there is sputum, careful, competent microscopic examination is a guide, though not an infallible one, to diagnosis. Still less is it an infallible guide to prognosis. An early diagnosis is often the most important factor of a favorable prognosis. No subsequent skill can atone for want of promptness in diagnosis. An early hæmorrhage is apt to be a fortunate thing, for it will stop a man and cause him to follow advice as nothing else will. These incipient cases frequently do well at home, if the regulation of food, ventilation, and exercise is looked after in all detail; but the greater number do best when they are sent to some very moderate altitude (not over two thousand five hundred feet), watched, their mode of life carefully controlled, then worked up to some decided altitude (five thousand to seven thousand feet). The commencement of this progressive climatic treatment may be in the Eastern mountain ranges, if the season of the year is suitable.

Southern California, in its varying degrees of dryness, elevation, and warmth, promises well for these cases. I believe many of this class of cases would do well to advance to the Rocky Mountain region after a few months passed in this region. One can experiment with altitude here and get out of it in an hour if it doesn't work. The cases of early hæmoptysis need no special separate consideration. The same management holds good for them. Altitude, even a high altitude, is not contra-indicated.

B. Those with considerable consolidation of recent formation, but with no marked disturbance of pulse and temperature, do well at a dry level of two thousand or three thousand feet, and then, when tolerance and quiescence are established, a higher location for a while. Again Southern California presents a favorable place for many of these cases at first and perhaps indefinitely. It appears unwise and will be found difficult to send one who is doing well to another place, but at the proper juncture a visit in the Colorado country is frequently of the greatest service. In a convalescent from pleuritis, where there is much deposit and where from family history or other causes we fear tubercular degeneration, most happy results are often obtained in an altitude of five thousand to eight thousand feet; in this and all other instances, providing the heart is healthy and the nervous system unimpaired.

C. Those very sick, either from advanced disease or active involvement of much lung tissue, had better remain at home, unless great wealth puts them outside the pale of ordinary mortality.

D. *Emphysematous Cases.*—The best climate for the emphysema of a phthisical lung is that which best suits the bronchitis which goes with it. There is wide space for experiment. These people do not often do well at any altitude, and should not be sent there until a low, warm, moderately dry location has been tried and has failed. Some points in Southern California answer well, and so should many places in the South Atlantic States.

E. *Laryngeal Cases, i.e.*, those in which the symptoms and signs of tubercular ulceration of the laryngeal structures are prominent features. I do not refer to the early laryngeal irritation which often marks the inception of phthisis and which frequently disappears as the lung lesion advances. Any considerable elevation is disastrous to true laryngeal cases, though once in a while we see one do well in the mountains. A warm, even, not too dry climate suits best, though the parched desert at the sea-level meets the wants of a few. Often even where the dampness hurries on the destruction of lung, the relief from laryngeal pain makes it desirable to live at the sea. No place offers more than Southern California for this class.

F. *Cases in which the Formation of Fibrous Tissue is Marked.*—Thorough study, nice discrimination, and some experimenting are needed in adjusting these cases in their proper places. Do not send them to an altitude if they are beyond middle life or if there is much bronchial irritation or if their hearts are dilated or feeble. If none of the above conditions exist, they may try the Colorado or Rocky Mountain country, using great discretion and restraint in bodily exertion. The wide range of choice found in this country renders Southern California desirable for this class.

These six groups will include almost all who come into our hands.

Certain complications must modify our counsel. Elderly people, those with diseased or feeble hearts, cases of nephritis or of tubercular ulceration of intestine, are not apt to do well at any elevation over three thousand feet. In seeking health from climate, it must be ever remembered that it is all out of doors and must there be sought. If the open air in these "resorts" is good, the indoor air, from faulty construction and carelessness, is bad. This goes far to explain why men do better than women.

As to the treatment of phthisis by drugs, there is only space for a word. During a prolonged case, almost every drug may be reasonably called into use, and if used with discretion, do good. It is with drugs, as General Sherman is reported to have said about guns: "It isn't the kind of gun, so much as the kind of man who holds it." The stomach is to be treated

with the utmost consideration, and anything that for an hour interferes with its functions should be withheld, unless there is imperative need for the relief of some particular symptom. That "two bad lungs and a good stomach are better than one bad lung and a poor stomach" is a homely expression often heard where consumptives gather.

The proper management—I do not call it treatment—of phthisis pulmonalis is embraced in these words: To build up and maintain the integrity and restrictive power of each cell in the body. There is no one point more important or so commonly overlooked as the regulation and restriction of exercise. The treatment by rest, absolute rest, even rest in bed, in the early history of the febrile cases, far outshadows all others in importance. At first this seemed to me especially necessary in the Colorado altitude, but subsequent observation would indicate that it is equally important at all levels. If one cannot be sent to a distant climate, let every effort be made to get all the good out of the one to which the invalid is confined. I knew a man with decided lung disease, who unsuccessfully went the rounds of all the places and went back to end his days on a sunny porch in Boston—and got well there!

As to the Communicability of Phthisis.—Consumptives as a class like to tell where they "caught it." It is definite, positive, and in a way puts the blame on somebody else and so fills a long-felt want. How many physicians have seen an authentic case where a perfectly healthy person contracted the disease from an infected one? I know of just one where it was probably so acquired, and that is the only one of scores where the claims of infection had been set up where the evidence was at all conclusive. After severe strain, nervous or physical, we all see the disease, as it were, grafted on to the debilitated organization. Whether this happens oftener when a consumptive is in close attendance than when absent I do not know.

The following extract from a letter from one who has had ample field of observation, voices the opinion of those whose special knowledge led me to ask them: "As regards your question ('Have you observed consumption to be communicable?') I am most emphatic on this point. I have never seen a case where I have thought that there was a reasonable ground for assuming that phthisis pulmonalis had been communicated from an infected person to one previously healthy. I have seen but few cases where there could be a suspicion, and inquiry would usually develop the fact thas there had been excessive strain, nervous or physical, *e.g.*, from nursing, inducing a debility and low resistance and then exposure to cold or something of the sort. I have seen many a case where a consumptive husband or wife lived in the same room with and even slept with a healthy husband or wife and I never knew any bad results in the way of inoculation or infection to follow."

This does not go to disprove that the feeble are in danger from the tuberculous. No attempt in that direction is intended. It does not in the least remove the need of most vigilant cleanliness. Every atom of tubercular or suspected sputum should be destroyed by chemicals or fire, but it enables us to say that the nineteenth-century consumptive may be safely treated less like a leper than the clamor of lay science at present demands. Some of us are cultivating a broad receptivity of mind on the subject of the significance of the bacillus tuberculosis. We may be a little slack in our allegiance to his sovereignty, but we all pay tribute. Even the chief sceptic would prefer not to have the rods in his sputum. However much pulmonary tuberculosis at the bedside may differ from that in the laboratory, it is to those who are working along the trail that Koch blazed out, that our eyes are turned in hopeful expectation.

My apologies are due for the triteness of this subject, but triteness in matters medical is sometimes synonymous with importance. It is a great subject, and there were a dozen places as we came along, where we might have stopped and discussed some point barely noticed, but it cannot be done at one sitting. If you have had to listen to what you know as well already and could have said better, it may be a consolation to recollect that it is a risk everyone runs who goes to medical societies.

Progress of Medical Science.

Primary Carcinoma of the Duodenum.—Dr. Pic has made a comprehensive study of this subject, as a result of which he has formulated the following propositions: *A.* Primary cancer of the duodenum, in the great majority of cases, like primary cancer of the intestine in general, has an annular form. On this account it is very apt to produce stenosis of the digestive tract. *B.* The symptoms of this cancerous stenosis vary according to the height at which it is produced. A cancer above the ampulla of Vater has a symptomatology almost identical with that of cancer of the pylorus. A cancer below the ampulla presents, besides symptoms of malignant pyloric stenosis, signs indicating a permanent reflex of the bile and the pancreatic juice into the stomach. A cancer round the ampulla presents, according to the case, a symptomatology more or less resembling the one or the other of the first two forms; it is a composite form. *C.* Among the so-called cancers of the ampulla of Vater we may place: 1. Cancers of the duodenum in which the ampulla is invaded; nothing distinguishes these tumors clinically from ordinary duodenal cancers; they are included in our third form. 2. Cancers primary in the head of the pancreas. 3. There exist some cancers appearing to be developed at the expense of the ampulla, and presenting the clinical picture of icterus from retention—a picture comparable to that of cancer of the head of the pancreas. These cancers must be distinguished clinically and histologically from cancers of the duodenum strictly speaking, and must be classed with pancreatic cancer, of which they appear to constitute aberrant varieties. 4. *a.* In most of the cases there is a contraction at the site of the tumor and a dilatation toward the stomach tending to involve this organ, and frequently accompanied by pyloric insufficiency. *b.* The histological examination has revealed up to the present, among the primary tumors of the duodenum, cancers of the investing epithelium type (cylindrical epithelioma), of the glandular type (primary epithelioma of Brunner's gland), of the embryonic-tissue type (sarcoma), and of the lymphatic type (lymphadenoma). As a matter of fact, there are forms of cells entering into the constitution of the duodenum other than those found in these forms of cancer. 5. The difficulty of diagnosis in cancer of the duodenum varies according to the situation of the neoplasm; while the diagnosis of the form which occurs above the ampulla is ordinarily impossible, that of the two other forms is sometimes possible. Speaking in a general way, the chief differentiation is to be made between duodenal cancer and stenosis of the digestive tube of supra-duodenal or infra-duodenal origin, and between duodenal stenoses of extrinsic origin. 6 The topographical diagnosis is of greatest importance from an operative point of view, which will differ according to the situation of the neoplasm in the duodenum. When the diagnosis is impossible early exploratory laparotomy will be necessary, and in most cases will be only palliative.—*Revue de Médecine.*

Poison Labels.—In Ohio there is a law making it obligatory on dealers to affix the label "Poison" on all bottles of household ammonia sold.

MEDICAL RECORD:

UNNECESSARY NOISES.

In a recent issue of a daily paper there was a report to the effect that a sneak thief who successfully raided a boarding-house escaped detection by purposely making as much noise as possible in order that he might be mistaken for a belated lodger. The result proved that there was no better way to quiet the apprehension of anything unusual than the creation of an ordinary racket and the well-known receptive resignation to its usual disturbing tendencies. There is in the circumstances all the necessary proofs that not alone in lodging-houses but in every other environment of our so-called advanced civilization the denizen of a crowded city has become so inured to the discipline of noise that he submits to it as a necessary evil.

The interesting question comes up in this connection as to the distinction between necessary and unnecessary noises. The former can be made tolerable by reason of their inevitability, but the latter are always exasperating by their easy preventability and consequent uselessness. When we stop to consider what noises can be dispensed with without harming anyone but the maker of them we open up an astonishingly wide field of inquiry. From the snoring bed-fellow to the noisy neighbor there is all the difference between the awakening elbow-punch in the rib and the remote possibility of a floral gift for a waiting coffin. But the application of such or similar means are so seldom made in this cruel world of chance that practically the real remedies are very few. Still less is this the case with noises apparently beyond our reach. The clamor of traffic is in some respects a necessity of the struggle for living and gain. The useless accessories of such a situation are too numerous to mention. Take for instance the numerous street cries of pedlers, the roar of the elevated train, the clang of the cable car, the irritating factory whistle, the intrusive hand-organ, and even the reverentially suggestive church-bell.

Not long since a piano fiend in an adjoining house rendered miserable the dying hours of an honored judge in brazen defiance of frequent protests from his bereaved family. We wonder if it be true, as the Swedenborgians assert, that pianos will be allowed in heaven. If so, it may be possible to assume that they will be tuned to a harmony unknown and unrecognizable by earthly mortals. In any event the only hope will be that the practising miss with her dreary and exasperating finger drill may not die before she is well started with a tune. The piano, however, has done more to educate humanity into a forced toleration of disagreeable noises than any other known agent in the prodigal inventions of the nineteenth century. The discipline of forbearance that it has inculcated in the human breast has so overwhelmed the disposition to profanity toward all other comparatively trifling inflictions that there is a grim satisfaction in believing that this instrument has very indirectly and quite innocently helped to develop a high grade of self-sacrificing Christian charity. All of these, however, come under the heading of really unnecessary and apparently preventable noises. Much more pronounced ones that are evidently without remedy are resignedly and philosophically borne, and the very uselessness of prevention is in itself a solace of tolerance. The man who can sleep peacefully through a rattling thunder-storm loses all somnolent composure while his neighbor is filling a bath-tub, or noisily tumbling over bedroom furniture. The traveller who could composedly sleep in the berth of a limited express train would suffer the wicked suggestiveness of infant mortality while listening to the wakeful cry of a restless baby.

Strange to say, however, all these disturbers of the peace, with much show of injured innocence, are ever ready to act upon the defensive in what they consider their rights and privileges. The struggle of the brass band to maintain its boisterous hold on the street curb is still fresh in the mind of the long-suffering New Yorker. Luckily for the latter the stuttering voice of the brazen funnel is relegated to "innocuous desuetude." Many of the street cries have been abolished after similar struggles in the cause of quiet-loving persons. Let us hope that many more reforms will follow in their wake.

It is unnecessary to allude to the wide-spread evil effects of noise upon the public health. If the accumulated agony of irritability could find a common voice it would dangerously jar the equilibrium of the public peace. The only mercy is that it has so many different vents through the thousand channels of individual protests that a general explosion of wrath is thereby averted. Appeals are often made to the Health Board for the suppression of such noises as may be construed as prejudicial to health. Practically all unnecessary noises are such, although the police catalogue places many under the designation of disorderly ones. The difficulties in the way of deciding which is which are not few. The Health Department, with all its arbitrary power, cannot seemingly make a politic distinction. This was shown in the case of the cruel pianist and the dying judge. Perhaps some day a proper test case may be brought for adjudication, but hardly until some enterprising neurologist can locate the noise-centre and conclusively prove the direct causes of its premature exhaustion.

Suicide of a Medical Man.—A surgeon lately practising in Bristol, England, was called to the door by a ring, but instead of the expected patient, found a collector for over-due rent. This so discouraged him that he killed himself.

WHAT SHALL BE DONE WITH ADVERTISING QUACKS?

With the present restrictions upon the practice of legitimate medicine, backed by the stringent examinations of the State boards, it becomes us to inquire how much the real and harmful quackery is prevented. Judging from the blatant advertisements in the daily papers it would certainly appear that medical rogues are rather on the increase than the decrease. There is such an inconsistency in all this, such a disposition to curtail the privileges of the virtuous at one end, and such marked apathy in guarding the dangerous practices at the other, that it almost seems as if the good must be punished for the sake of the bad.

The Medical Society of our own county has striven with commendable zeal to bring punishment on the offenders in question, but as yet has been unable to succeed. By virtue of old diplomas these advertising scoundrels are apparently protected by law—at least the County Society, so watchful of small offenders, cannot reach them by any legal process known to the counsel of that body. It is no secret that most, if not all, of these advertisers are professed abortionists, and have from time to time been under arrest on such charges. They constantly escape a just punishment, and the very indictment is oftentimes used as a means of wider advertisement of their nefarious practices. No newspaper, however respectable, refuses their standing advertisements, and even the religious weeklies pander to them under the hypocritical guise of covert endorsement. These latter journals, particularly, trusted with the responsibility of guarding the physical and moral safety of the community, allow the quacks boldly to announce for sale quick cures for "gonorrhœa," vegetable tonics for "falling of the womb," infallible pills for "female irregularities," and patented belly-bands for "seminal weakness and the decline of manhood." Aside from the positive damage which such advertisements may occasion by false pretences and actual bodily harm, we are forced to contemplate the still greater injury to morals of the rising generation by a free, forced, and covert education along these dangerous lines. While all this is going on in the broad light of day, and under the very noses of our medico political reformers, we learn that a respectable well-educated physician cannot remove his practice from one county to another in this or other States without suitable legal license and registration. It is true that the New York quacks cannot practise anywhere else than in the county they reside, nor do they, for obvious reasons, care to do so. There is no better place in which to ply their abominable trade than in this city. Their only desire is to be left alone. It has always been a puzzle how professed abortionists can go on, apparently for all time, undisturbed, when any respectable practitioner dares not respond to a purely professional call in a case of emergency, the result of these criminal practices, without the protection of another professional man as a witness and without a preliminary notification of the fact to the Coroner. It would seem more just that the power of the law should be on the side of the righteous rather than on that of the evil-doer. The same law that imposes restrictions upon qualified men should protect them against the outrageously wicked machinations of the evil ones. There should be no stretch of power in the law in one direction more than in another. If any law can be so framed as to restrain the privileges of the well-qualified in certain directions there is no reason why similar means could not be used to prevent the quacks from openly defying every enactment that has thus far been made. We respectfully call the attention of our medical law-makers to this matter, and more especially would commend the latter to the consideration of the county societies, which have volunteered to guard the higher interests of medicine and to guarantee a riddance of reprehensible practices.

HOW TO BEGIN PRACTICE.

The all-important question how and where to begin practice is one that every young medical man must settle for himself. The considerations that should govern him are as much of a strictly personal as of a purely professional character. At best it is but an experiment, the success of which largely depends upon such conditions as only time and opportunity can properly develop. Of one thing he must convince himself at the outset, and that is, inasmuch as the profession is very much overcrowded, the community at large is not over eager to test his abilities, or anxious, in view of his supposed eminent fitness for his work, to find him an easy or safe living. He must necessarily create a place for himself and with a reasonable persistence of purpose develop his own plant. If he be content to commence in a small way and be satisfied with slow advancement he is likely to succeed in any neighborhood, whether in the country or city. The better chances are those in a young and growing locality, neither rich nor poor, but rather among people of the middle class. The latter are generally prompt in the payment of the smaller fees that must satisfy the younger professional man. The very poor patronize the dispensaries and the very rich are generally already well provided with specialists in every branch and a family physician besides. There is no greater mistake for a young medical man with limited means than to settle in an expensive and fashionable neighborhood in the expectation of gaining, thereby, a first-class practice in the beginning. As a rule, the rich will entirely ignore him and the poor will be afraid of his style and assumed superiority of living. The people who are likely to employ him at all will be satisfied with a moderate establishment and will be proportionately impressed with his earnest business spirit.

The choice of city or country depends largely on the personal habits and tastes of the individual. Country practice, strange as it may appear, demands a higher grade of general professional attainments at the start than those by which a young man makes an ordinary success in the city. In the country the young practitioner must from the very nature of his business be a good all-round man, prepared for any ordinary emergency in medicine, surgery, or obstetrics, while his city brother, surrounded by experts, can very readily divide extra responsibilities. The former is a marked man

from the beginning, is generally known by everyone in his town, and must necessarily at the very commencement of his career set the pace for the remainder of his life. On the other hand, the metropolitan youngster, as far as a general reputation is concerned, is pretty sure, in his earlier struggles at least, to be lost in a crowd. The returns for work in the country are generally more prompt than in the city, and sooner reach their absolute limit, while the rewards in the city are slower and in the end are proportionately expansive. It is quite uniformly agreed that general practice is the best surety for a good start anywhere, and in a large city the most thickly populated portions are to be preferred. There is something in the cosmopolitan character of such districts that takes a young and struggling practitioner on his merits, and is as ready to shift to the newcomer as stick to the old timer. It is excellent training ground until enough money is made to move into a better neighborhood. In any event, wherever, whenever, or however a young man begins it is well to bear these cardinal business points always in mind: stick, watch, wait, and work.

TOBACCO AND RELIGION.

It is somewhat startling to learn that peace has been in a measure declared between tobacco and religion, and the former, that has been so often declared to be the ally of the evil one, is about to join forces with Christianity in its laudable effort to evangelize the world. Not very long ago, at a ministerial conference, it was voted that no minister of the gospel could consistently preach with a so-called tobacco breath, as it was impossible under such circumstances to maintain that odor of sanctity and earnestness of persuasion necessary for successful spiritual ministrations. We believe one good brother rather forcibly alluded to the impossibility of drinking pure water from a foul cup or mug. Although no originality was claimed for the allusion, it had the telling effect of securing the passage of a resolution forbidding the parson from smoking or chewing the so-called noxious weed. It is fair to say that the cause of the smokers and chewers was not lost without a struggle. Many, however, knowing the impossibility of sincere and effectual repentance of the habit, sought relief in that usual mental reservation of possible wickedness in private as contrasted with plausible virtue in public. In fact one of the committee, in copying the resolutions in a side room, was charged with actually smoking while so engaged. It was maintained on that occasion that no man with a quid in his teeth could properly round his periods or decorously control labial reflexes with a mouthful of redundant saliva. Certainly no man caught in the act could pose as a shining example of ordinary Christian self-denial.

Now, however, it would appear that the tobacco aspect has entirely changed front. We notice a report to the effect that in one of the London churches there has been established what is called a smoking service, in which the habit is not only tolerated, but actually encouraged by an extra offer of free tobacco. This innovation will doubtless act as a powerful temptation to many outsiders, and may, we trust, tend to overcome any scruples as to waste of time in listening to prosy sermons, while at the same time the smokers themselves may become more benevolently receptive to those better influences that associate themselves so directly with the other forms of church service. The smoker, with his pipe well aglow, is generally prepared to look on the reasonable and happy side of any question. Many an after-dinner speaker is saved from well-merited condemnation for prosiness by the benevolent tolerance of a crowd of smokers. Tobacco, under the circumstances, tones down antagonism, paralyzes criticism, and invites conviction. Thus the tobacco service is likely to be a success in every way, provided the tobacco itself is of good quality and the smoking service of satisfactory length to the old stagers.

News of the Week.

The Late Professor Thomas Henry Huxley was a graduate in medicine, having received the degree of M.D. in 1845 from the University of London. He stood second in the list of honors for anatomy and physiology. He joined the medical service of the navy in 1846, and was surgeon to The Rattlesnake during its trip to Australia and New Guinea. Professor Huxley left the naval service after seven years, and during that time he studied natural history much more than he did medicine. His earliest ambition was to be a mechanical engineer, and he studied medicine rather against his will. In his autobiography he says: "I am now actually horrified to think how little I ever knew or cared about medicine as the art of healing. The only part of my professional course which really and deeply interested me was physiology, which is the mechanical engineering of living machines." Professor Huxley's only work having a special interest to medical men, as such, was his "Lessons in Elementary Physiology," which was a very good introductory manual when first published, now thirty years ago.

Dr. Edward R. Palmer died in Louisville on July 6th of injuries received while riding on a bicycle. He came in collision with another wheelman. Dr. Palmer was President of the Genito-urinary Section of the American Medical Association. He was born in Woodstock, Vt., and went to Louisville forty-four years ago.

Gratesetters' Neurosis.—Dr. E. C. Runge describes, in the New Albany *Herald*, the case of a man who suffered from a peculiar forward jerking of both legs, which was most apt to occur after he had been sitting for some time, but which also took place when he was occupied in reading or playing games, and even when he was asleep. For twenty-four years the man had followed the business of setting grates, and had worked in a kneeling posture, frequently for ten hours at a stretch. Dr. Runge suggests that this peculiar spasmodic disorder, which was associated also with some neurasthenic symptoms, should be classed among the occupation neuroses.

Examinations of the New Jersey State Board.—At the June examinations of this Board, over forty per cent. (eleven out of twenty-six) of the candidates examined for license to practise medicine in New Jersey

were rejected. One candidate was dropped before the examination was completed, for "cribbing."

American Orthopedic Association.—The ninth annual meeting of this Association will be held at Chicago September 17, 18, and 19, 1895, under the presidency of Dr. John Ridlon, of that city. An interesting programme is promised.

Prophylactic Measures Against Tuberculosis.—At a recent meeting of the Berlin Medical Society, Professor Cornet read a paper on the above subject (*The Lancet*). He had already suggested that the tubercle bacillus is not ubiquitous, as some observers suppose, and is present only where phthisical patients have expectorated and where the dried sputum has afterward become dispersed. This result he had arrived at by very extensive examinations of the wards in hospitals, and the rooms in barracks, prisons, and monasteries, where crowds of people live together in a limited space; the dust and mud of the street were also carefully examined by him. In rooms where spittoons containing some water were in use he very seldom found the bacillus, even if the phthisical patients lived there. According to him the prophylactic measures are very simple: a large number of spittoons partially filled with water should be provided in order to prevent people from spitting on the floors, and handkerchiefs should not be used for receiving expectoration; moreover, the floors of houses and the streets ought to be sprinkled with water as often as possible. Heredity had less influence on the origin of tuberculosis than was generally believed. In a great many cases where the children of phthisical parents were attacked with the disease, the communication might be due, not to heredity, but to mere contagion. The number of those suffering from phthisis is, in Professor Cornet's opinion, estimated to be higher than the results of necropsies warrant. It is an error to suppose that the atmosphere is filled with tubercle bacilli; they are dangerous only where the necessary precautions are neglected. In proof of the efficacy of hygiene in reducing the danger of tuberculosis, Professor Cornet mentioned that on his advice the Government had taken the above-described measures to prevent the general dispersion of sputum in prisons and lunatic asylums, and that since this time the mortality had fallen considerably.

A Systematic Study of the Therapeutics of Leprosy.—The Board of Health of the Hawaiian Islands has lately established a small hospital at Kalihi, in the outskirts of Honolulu, and has begun a work which has for its purpose the solution of the questions: "Is leprosy curable?" and "What are the best means for its relief and eradication from the human system?" Twelve patients selected from the leper colony at Kalawao, on the Island of Molokai, have been placed under treatment at the Kalihi Hospital, where they are provided with an abundance of wholesome, nutritious food, clean bedding in airy rooms, and the opportunity for outdoor exercise and recreation. There is also an abundant supply of pure water, and the use of hot and medicated baths will be an important feature of the treatment. The many several remedies which experience has pointed out as of use in combating this formidable disease will be tested in the treatment of the patients, and their efficiency carefully noted. Careful notes have been taken and photographs made of the patients, and the histories will be continued during the different stages of the treatment. The "Committee on the Treatment of Leprosy," which has undertaken this investigation is anxious to enlist in its aid the interest and intelligent co-operation of all members of the medical profession, and invites suggestions as to both means and methods from all who are interested in the study of leprosy. It is purposed to publish, when the proper time comes, a bulletin or report of progress regarding the work. In the meantime the Committee would be glad to enlarge its acquaintance with the bibliography of leprosy, and to be put in the way of becoming the owner of various monographs on the subject as they are published. The secretary of the Committee is Dr. N. B. Emerson, Honolulu, H. I.

The Chautauqua County Medical Society held its annual meeting for 1895 at the Thompson House, Mayville, N. Y., on Tuesday, July 9th. After the meeting the members adjourned to the Kent House, at Lakewood.

The Late Dr. Alexander I. Aronson.—At a meeting of the Eastern Medical Society of New York, held June 28th, the following resolutions were adopted:

Whereas, Our friend and beloved colleague, Dr. Alexander I. Aronson, who was so highly esteemed by all who knew him, as to his professional ability, reputation, and honesty, has been suddenly called away to his eternal rest; and

Whereas, The Society has lost a member and sincere friend, whose place will be difficult to fill, and his family loses a blessing father and loving husband;

Therefore, be it Resolved, That we all regret the sudden loss of our late colleague, and that we all mourn our loss, that we extend to the family our heartfelt sympathy and sincere regret in this sad hour of affliction; and it is further

Resolved, That a copy of these resolutions be spread on the minutes of our society, and a copy be sent to the bereaved family of our deceased colleague, and that they be published in the medical and local press

H. B. Adler, M.D., *President.*
E. K. Browd, M.D.,
M. Caspe, M.D.,
M. D'Avidoff, M.D.,
M. Burstein, M.D.,
S. Brothers, M.D.,
Committee on Resolutions.

Sero-therapy of Syphilis.—Those who have watched the various ingenious attempts to treat syphilis by the application of sero-therapy, have become aware that it is very manifest that nothing has been accomplished of any practical value.

Nocturnal Enuresis.—Dr. Stumpf has suggested a simple expedient for the treatment of nocturnal enuresis. It consists simply in raising the hips of the child, so that it sleeps with them elevated at an angle of 130° to 150° with the horizontal spine. This is accomplished by placing one or two ordinary pillows under the thighs. The theory is that the urine is kept from getting into the urethra, when the sphincter is relaxed during sleep.

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-first Annual Meeting, Held in Boston, June 5, 6, and 7, 1895.

DR. PHILIP COOMBS KNAPP, OF BOSTON, PRESIDENT, IN THE CHAIR.

FIRST DAY, WEDNESDAY, JUNE 5TH.

President's Address.—THE PRESIDENT thanked the Association for the honor conferred upon him, extended to them a welcome to Boston on the occasion of their first visit to the city, and offered them greetings from the various honorary members abroad.

The Association was organized twenty years ago, with a membership of thirty-five. At that time the idea of such a society was something of an experiment, as few similar societies existed in the world. The society, however, had been successful, had increased until there were now eighty-five members, and the meetings had always been profitable and interesting. It was not a society limited exclusively to specialists, as all who were interested in the diseases of the nervous system had been welcomed to its ranks.

The scientific work done by the members of the society was briefly reviewed. The chief work done in this country, with reference to diseases of the mind and nervous system, had been done by members of this Association. In regard to investigations in the anatomy and physiology of the nervous system, the work done in this country was still below that done abroad, and endowments for such research were considered desirable. The work done in the study of disease and its manifestations, and in the treatment of nervous diseases, had been much greater. American neurologists had done very much to advance our knowledge of the treatment of disease of the nervous system, and no discovery in the last twenty years had been of as much importance as that of the rest cure by one of the members of the society, Dr. Weir Mitchell, of Philadelphia.

Some of the needs for work in the future were then pointed out, among them being the need of a journal, under the control of the society, and greater recognition in our large hospitals, and a greater knowledge of nervous diseases by the physician in general practice. The greatest hope for the future in the treatment of nervous diseases lay in prevention. Many of the most serious affections were secondary to infectious diseases, and therefore, with the greater knowledge in the prevention and treatment of these diseases would come a diminution in the amount of nervous diseases due to them. In many cases where people acquire nervous diseases on account of a defective nervous organization, it was considered advisable to put such people under a definite prescribed existence. There were many conditions of life which did no harm to the healthy man, but against which such persons should be protected. These persons should also be protected from the mental contamination of neurotic and degenerate influences, whether in morals, religion, art, literature, or sociology.

There had been much claim of a vast increase in nervous diseases at the present time, but it did not seem probable that the conditions of life to-day were more exacting than those of life in the past, and, with better food, more rational standards of living, and greater security for life and property, it seemed not improbable that there was an actual diminution in the amount of nervous disease.

Hysterical Amblyopia and Amaurosis.—DR. J. ARTHUR BOOTH, of New York, reported four cases of this affection successfully treated by hypnotism.

DR. F. X. DERCUM, of Philadelphia, thought it of interest to note that perception of light was normal in these cases. In his experience, reversal of the color field is not common, and does not occur as often as supposed.

DR. MORTON PRINCE, of Boston, asked if the patient's vision was tested during the hypnotic state. In his opinion, the theory of a shutting off of consciousness during hypnosis is a correct one. In many of these cases, binocular vision is preserved, as proved by prism and stereoscope.

DR. G. L. WALTON, of Boston, said that experiments seem to point that these cases really do see. The tests, however, do not prove that these patients are not simulating.

DR. BOOTH, in closing the discussion, replied that all of his cases were tested for binocular vision, but it was found absent. There was no cause for simulation.

Complete Hysterical Anæsthesia in the Male.—DR. PRESTON, of Baltimore, read a paper with the above title. The case related was that of a man aged thirty-one. Family and personal history were unimportant. The man was a moderate drinker, and during a spree got into a fight, but received no injuries other than some slight bruises. A day or two after admission into the hospital he developed a small patch of anæsthesia of the scalp. A few days later, general anæsthesia appeared. There was complete loss of tactile and pain sense as well as temperature sense. Muscular sense was greatly impaired, but not entirely lost. Taste and smell were lost, and hearing impaired. There was great constriction of the visual fields, and the color fields were reversed. Reflexes, superficial and deep, were normal, as was the electrical reaction. The patient gradually improved and finally recovered under hypnotic suggestion. Total anæsthesia is a comparatively rare condition if the cases of transient loss of sensation be omitted. Stress was laid upon the importance and reliability of careful examination of the visual fields.

DR. GEORGE W. JACOBY, of New York, thought that cases of total hysterical anæsthesia are not rare. They are most frequently found in cases of insanity. He referred to the case of a young girl, in whom he endeavored to determine the presence of ataxia, but it was not demonstrable. In the patients that he had observed, there were also painful points on deep pressure.

DR. WALTON considered it unsafe to depend upon constancy of tests as establishing genuineness in cases of supposed hysteria. A clever simulant may pretend an anæsthetic boundary, sufficiently constant to fall within the limits of genuine variation.

DR. WILLIAM M. LESZYNSKY, of New York, said that with proper precautions during the examination, and with our present methods of investigation faithfully and persistently carried out, it was impossible for the cleverest patient, even an accomplished ophthalmologist, to successfully simulate defective visual fields.

DR. J. J. PUTNAM, of Boston, believed that persons in apparent health are hysterical to a certain degree. The diagnosis must be made from the general aspect of the case, and not from any single symptom.

DR. W. A. JONES, of Minneapolis, asked if there was any immobility of the eyeball in Dr. Preston's case.

DR. J. MADISON TAYLOR, of Philadelphia, asked if there was any difficulty in locomotion, more particularly under excitement.

DR. PRESTON replied that there was neither immobility of the eyeball nor difficulty in locomotion. The muscular sense was preserved and there was no ataxia. He had observed total anæsthesia in one case of insanity. He thought we were too likely to neglect a careful study of the central organism, while devoting so much time to the periphery.

Railway Spine.—This was the title of a paper by DR. F. X. DERCUM, of Philadelphia. He reported two cases with autopsy. In the first case there was excessive sprain of the muscles of the back and of the

trunk generally, with marked spasm of the muscles, and tremor, together with increased reflex excitability of the muscles and tendons. In addition, the symptoms so commonly observed in traumatic neurasthenia were typical; namely, disturbed sleep, startling dreams, sudden awakening with fright, excessive sweating, frequent micturition, occipital headache, tinnitus aurium, marked general weakness, etc. The patient died from some intercurrent disease. Careful examination of the nervous system showed no demonstrable lesion. In the second case there was severe traumatic left brachial neuritis and left brachial monoplegia, with atrophy of muscles about the left shoulder. Severe sprain of muscles of back; right hemi-analgesia extending from the foot up to the level of the nipple; right hemi-thermo-anæsthesia extending from the foot up to the level of the false ribs. The man was exceedingly weak physically, but mentally he seemed clear and accepted his situation in a philosophical spirit. He died suddenly from the rupture of an aortic aneurism. The post-mortem examination of the nervous system proved negative.

Dr. Joseph Collins, of New York, said that although the autopsy and subsequent histological investigation did not succeed in unravelling the mystery of the real basis of the traumatic neuroses, the cases are instructive because of the negative findings. He was in the fullest accord with Dr. Dercum, as to the futility of attempting to demonstrate the organic basis of these diseases by means of older methods of investigation, more particularly by any such as require hardening in Muller's fluid for their preparation. In the first place, this procedure allows no cellular stain except the carmine, and this is so inferior to the Nissl stain that there should be no reason for using it; and in the second place, even if it were a good one the changes that go on in the structures which it stains, from lying for several months in a watery fluid, are such as to negative any conclusions that might be drawn from possible findings.

In one of Dr. Dercum's cases, the ponto-bulbar symptoms were so pronounced—the facial twitchings, the hemi-atrophy, the sensory disturbance—that it was extremely likely that some anatomical change was at the bottom of it. It seemed to him, moreover, that the presence of the large aneurism, which in all probability was of traumatic origin, would indicate that the changes in these cases are primarily vascular.

Dr. Charles K. Mills, of Philadelphia, looked upon these negative results as being very valuable. The microscopical examination should, however, have included the dorsal spinal ganglia.

Dr. Prince said the paper contained a direct proof of the theory of the traumatic neuroses. These patients suffered from psychical shock and physical shock. He agreed with Dr. Collins as to the method of study of nerve-tissues.

Dr. Edward D. Fisher, of New York, reported two similar cases still under observation. He believed there must be some pathological changes to account for the symptoms in many of these cases.

Dr. Smith Baker, of Utica, expressed the opinion that at the time of the accident there is a psychical copy formed which perpetuates this as a series of mimicry. A fixation of attention results, and may bring about changes in the higher cortical centres.

Dr. L. C. Gray, of New York, thought that the nature of these cases is still very puzzling. The term hysteria is objectionable. These railway cases are, however, not hysterical.

Dr. F. F. Miles, of Baltimore, said we will cease to record diseases as functional. The protoplasm of the neuron is altered in its activities by shock. Protoplasm has a tenacious memory (as we see when we have once taught it to make antitoxins) and may repeat an abnormal process until it is fixed by material change. The mystery is why this takes place in some cases of shock and not in others, and why this memory is perpetuated in the cell.

Dr. Dercum, in closing the discussion, fully realized the imperfect method adopted in preparing the specimens, but this was due to unavoidable circumstances in connection with the autopsy, and not from lack of familiarity with the newer methods.

Dr. M. Allen Starr, of New York, then gave a lantern exhibition of photo-micrographs of nervous histology, Golgi stains. This was followed by a lantern exhibition of the medulla oblongata of a chimpanzee with other specimens, by Dr. Edward Wyllys Taylor, of Boston.

Exhibition of the Brain of a Chimpanzee, by Dr. Thomas Dwight, of Boston. He spoke of the brain of the chimpanzee "Jumbo," and discussed chiefly the anterior limb of the fissure of Sylvius. On the left this was distinct, ending in a bifurcation beneath a rudimentary *pars triangularis*. On the right it was represented by a minute depression not connected with the fissure.

Inhibition in the Physiology of Respiration.—Dr. William Townsend Porter, of Boston, said that it is known that transverse division of the spinal cord between the bulb and the phrenic nuclei causes fatal arrest of the respiratory movements of the trunk. If death be prevented for a time by artificial respiration, the reflex powers of the cord gradually increase, and in the course of a few hours they may become so great that pinching the paws, blowing on the skin, suspending the artificial respiration, etc., may cause extended muscular contractions, including contraction of the respiratory muscles.

It is claimed that these contractions of the respiratory muscles after the separation of the cord from the bulb are proof that the respiratory impulse for muscles of the trunk is not derived from respiratory cells in the bulb, but originates in the spinal cord. Against this hypothesis of spinal respiration is urged the fatal arrest of the respiration of the trunk caused by separating the bulb from the chord. It is replied that section of the chord stimulates inhibitory fibres in the chord, and thus suspends the action of the spinal respiratory cells.

The doctrine of prolonged inhibition of spinal respiration is easily overthrown by the following experiment: Hemi-section of the cord usually arrests the contractions of the diaphragm on the side of the hemi-section. This arrest is not an inhibition, for the diaphragm on the side of the hemi-section begins at once to contract when the opposite phrenic nerve is cut. It follows that two hemi-sections, completely separating the cord from the bulb, do not inhibit the diaphragmatic respiration on their respective sides. The phrenic cells often send out no respiratory impulses after such a section, because they receive none from the bulb. The phrenic cells cannot themselves originate respiratory impulses. Hence the respiratory impulse does not arise in the spinal cord.

The Pulse in Insanity.—Dr. Theo. H. Kellogg, of New York, read a paper with the above title. It was based on the study of 2,172 cases of insanity, and gave tables and diagrams. The sphygmograms taken from among his patients on enamel paper had been transferred by photographic process, and were mounted on photographic cards.

The general conclusions arrived at were: that there is, in established cases of insanity, considerable increase in the average frequency of the pulse, both among men and women. The average obtained from the 2,172 cases was 84.8 per minute in the women and 80.8 in the men, giving a general average of 82.8 in the total number of patients studied. There was irregularity of heart action in five per cent., intermittence in two per cent., heart murmurs and heart lesions in eight per cent.

The various forms of sphygmographic tracings found in the different forms of insanity were discussed at

some length. The general result of the sphygmographic studies was that abnormal tracings are to be found at some stage of the disease in the vast majority of cases of insanity. They are due to affections of the cortical and spinal motor and vaso-motor centres, to various lesions of the sympathetic, to disorders of the pneumogastric, to peripheral and central vascular changes, to degenerations of central organs, to toxic agents in the blood, to auto-intoxications, to cachectic and diathetic conditions, to cardiac lesions, and to a great variety of intercurrent causes. No one sphygmogram is pathognomonic of any particular form of insanity, but there are certain general types of tracing which are found in one form of mental disease and not in another.

Localization of Lesions in the Pons.—Dr. Charles K. Mills, of Philadelphia, read a paper upon this subject. He first presented a record of a case with autopsy and drawings of microscopical sections. This patient was a man, fifty-three years old, with a syphilitic history. His intra-cranial symptoms came on about eight months before his death, the first being paralysis of the left abducens nerve. He had attacks of weakness and dizziness. He showed on examination paresis of the left leg and arm, paralysis of the left external rectus, paresis of the right external rectus with some restriction of ocular movements to the left. The patient was extremely emotional, tending to break into laughing and crying without special incentive. No areas of anæsthesia were discovered. The knee-jerk was exaggerated on the left side.

Examination of the pons and preoblongata revealed a lesion beginning about fifteen millimetres caudad to the junction of the pons and crus. It was on the left side, close to the median line, and almost entirely in the dorsal half of the pons. Sections through the lesions showed softened and degenerated tissue on both sides of the median line, much more marked on the left. As shown by microscopical examination, the parts involved in the lesion were the right mesal fillet and pyramidal tracts to a slight degree, and the root-fibres of the abducens. In connection with this case, remarks were made on the method of localizing small gross lesions in the pons. This method was founded upon a number of cases, most of which have been published. He divided each half of the pons and preoblongata into nine segments, three ventral, three dorsal, and three intermediate between the ventral and dorsal. Drawings were shown which were based upon actual sections of specimens. The parts played by the cranial nerves, by the superficial and deep transverse fibres, by the pyramidal tract, the fillet, the systems of root-fibres, and the nuclei of the cranial nerves and the special pontile nuclei in this method of local diagnosis were shown.

Second Day, Wednesday, June 6th.

Hyperostosis Cranii.—Dr. James J. Putnam, of Boston, read a paper with this title. He reported four cases of this rare disease, showing two of the patients, besides photographs and specimens illustrative of the other cases and of the disease in question.

The first part of the paper was devoted to a general discussion of the pathological questions, and the statement of the views expressed by Virchow, Baumgarten, and Starr.

Hitherto these enlargements of the cranium have been considered as of an inflammatory origin, but the two writers last mentioned have brought forward some reason for thinking that the disease may be a species of trophic affection, distantly analogous to myxœdema and acromegaly. This is an interesting hypothesis, but cannot yet be accepted as proved. The symptoms of the disease are mainly due to pressure by bony masses on the cranial contents, especially the nerves and vessels which perforate the skull. There is often exophthalmus, due to partial obliteration of the orbit, and usually some signs of paralysis or irritation of cranial nerves. Epileptic attacks occasionally occur, and sometimes very early in the disease. Double optic neuritis and other signs of intra-cranial pressure may be present, and there is almost always headache, due to the interstitial bony changes. The head is sometimes enormously enlarged, and when, as frequently happens, the bones of the face are involved, peculiar deformities may be present, such as suggested to Virchow the name "leontiasis ossea." Photographs of a specimen in Washington, illustrating this form of the disease, were exhibited.

Baumgarten pointed out that the disease generally began in youth, and in one of the reporter's cases the first indications were noticed when the patient was five years old, in the form of two exostoses near the vortex, which afterward assumed a great size. The cranial bones usually become very dense, as from an inflammatory change, but sometimes the diploë is rarefied. The question of operation suggests itself as a means of reducing intra-cranial pressure or of cutting off the blood-supply to the bone. In this connection it may be noted that the channels of the meningeal vessels are sometimes strongly marked, sometimes nearly obliterated.

Dr. Starr, of New York, said that these cases were more advanced and more extreme than those he had reported. He tried thyroid extract in one of his cases without benefit. He was led to do this as he had seen some improvement after its administration in a patient with acromegaly.

Dr. Morton Prince narrated the history of a case under his observation in which this condition of the cranium followed a traumatism which occurred two years before. The enlargement was not general, but was mostly confined to the frontal bone. At the autopsy the orbital plates were found enormously enlarged, and the anterior portion of the brain had undergone extreme compression.

Dr. G. M. Hammond, of New York, asked if structural changes existed in other bones. His case was of syphilitic origin, and there were nodosities and other enlargements in the long bones.

Dr. Putnam concluded that when syphilis was present these cases should be placed in a different class. There is a tendency to bony enlargements in these cases.

Dr. F. T. Miles, of Baltimore, showed the brain of a child, three and a half years old. It was from an idiot with left hemiplegia. The right cerebral hemisphere was atrophied to a great degree in all of its lobes and convolutions, and the right crus was small. The left cerebellar hemisphere was one-third smaller than the right.

Dr. H. L. Worcester, of Danvers, had made autopsies in three cases where there was decided asymmetry of the cerebral hemisphere, but the cerebellum presented no abnormity.

Dr. Charles K. Mills had reported, some years ago, the case of a negro murderer where there was atrophy of one cerebellar hemisphere with opposite cerebral atrophy. It is rare to find coincident atrophy of opposite cerebellum.

Dr. Starr said that this condition is usually congenital and is often found in idiots.

Dr. Edward B. Angell, of Rochester, had seen a similar condition at autopsy in a patient, thirty-three years of age, in whom a cyst of the cerebrum had existed since childhood.

Cortical Localization in the Light of Recent Researches into the Minute Anatomy of the Cortex.—Dr. Charles K. Mills opened a discussion on this subject. He said that the different theories as to the separate cortical localization of movements and of cutaneous and muscular sensation, which had been the

subjects of so much controversy, have again become prominent in the light of the researches founded upon the methods of Golgi, and particularly those made by Raymon y Cajal, Van Gehuchten, Schafer, Andriezen, and others. Those who contend against the doctrine that the Rolandic cortex is a purely motor region believe that they have received additional support for their views. The varying hypotheses with reference to the functions of the cortex were reviewed. He held that, as shown by Forel and Nansen, we have been too long handicapped by prevailing ideas of cell action, and by theories of the parts played by the cell-bodies as originating centres. Impulses are transmitted and transferred by processes as well as by cell-bodies, and the function of the latter is chiefly trophic. The new researches and theories he believed did not compel abandonment of former views as to special localizations, although different stand-points had been taken. Disregarding theory entirely, he believed that the subdivision of the cerebrum into physiological lobes—higher psychical, motor, sensory (meaning for the representation of cutaneous and muscular sensations), visual, auditory, olfactory, gustatory, and naming—remained for the practical purposes of the physician and surgeon the best. While the whole of the cortex in some of its strata may be regarded as a sensory expanse, if Rolandic portions and particularly the convolutions cephalad of the central fissure constitute a region which is related to specialized movements of various parts of the body. One calls it motor, another kinesthetic, another sensorimotor, and another executive, but for the purposes of the physician and surgeon it is a motor sphere, the irritation of which causes specialized movements, while its destruction impairs or abolishes these movements. He did not believe with Andriezen that it was necessary to regard the ambiguous and great pyramidal cells of this region, whose apical processes received the terminals of the fillet radiations, as the first sensory cells of the cortex. Indeed he regarded it as important to rid ourselves entirely of the idea of sensory cells and motor cells. The cortex contains localized areas. To abandon separate sensory and motor localization would, he believed, necessitate the abandonment of visual, auditory, gustatory, and other subdivisions of the cortex. The cerebral sensory area—that is, the area of representation for skin and muscle sensations—both cortical and subcortical, would be, from his point of view, that part of the cerebrum where the fillet radiations in their most compact forms are nearest to the surface of the brain, and therefore this region might continue to be described as it had been by him, as in the postero-parietal, quadrate, and formicate convolutions. Destruction of this region, especially if bilateral, caused more or less impairment of sensation. He referred to cases reported by Savill, Sharkey, Starr, McCosh, and himself as confirming this view. In the cerebrum, as in the spinal cord, were fields of junction between so-called cortical areas, and lesions of these fields of conjunction, or at the terminations of the sensory projection fibres, might give rise to temporary sensory phenomena; but persistent sensory disturbances were found only when the lesions involved the convolutions included by him in the general sensory area.

Dr. Dana said the author had not referred to or tried to explain the facts which establish the proposition that he believes regarding this subject. He (Dana) had collected a number of other cases and added some of his own, and it is because he cannot explain the clinical facts or the pathological facts by any other hypothesis than by supposing that the motor and sensory functions are practically united that he still holds to that view. He asked Dr. Mills to explain why, when one cuts away a section of the mid-central, pre-central convolution, he finds tactile anæsthesia and muscular anæsthesia the next day, with paralysis, on any theory except that these two functions are united in that spot. These cases are extremely numerous in the literature of neurology. If one carefully shaves off the anterior pre-central convolution in the middle part, he will get sensory disturbances, anæsthesias.

Dr. Mills may not perhaps be aware that in the living subject the motor cortex has been directly irritated also in front of the fissure of Rolando and produced sensory and motor disturbances. If a man's sensory functions are localized and the cutaneous sensations and muscular sensations are located in the gyrus fornicatus, he did not understand how the passage of the electric current should cause sensations entirely analogous in the arm to those of the tactile impression made upon the skin; in fact, the whole weight of clinical evidence is in favor of that view; the surgical operations, the tumors, the softenings, all are facts which cannot be explained on any other hypothesis, so far as he knew, than that the two functions are essentially identical anatomically.

It is a plausible theory that the visual centres, centre for visual sensation, and auditory and gustatory sensations, are separate from the motor sensations, and they and cutanous and muscular sensations would naturally have separate centres, but it does not at all hold against any actual facts, and when we come to analyze it it is not so necessary or plausible after all. The visual sensations are not so closely related to motion as are the cutaneous and muscular sensations. For the performance of co-ordinated movement we must have a very close anatomical relationship between the muscular and cutaneous sensations. They cannot afford to have muscular sense impinge on the gyrus fornicatus and have associated bundles running up to the central convolution. They must be close together anatomically for the purposes of a perfect machine, otherwise we could not make rapid motions; and he believed it is for that reason that nature had gradually shifted the sensory receptive cells so that they are in approximately close relation with the motor cells.

He believed that perhaps if we were all agreed as to exactly what is meant by sensations, and exactly what tests we use for making sensations, and were agreed about the terminology of our discussions, we would not perhaps have so much discussion about this matter. He agreed with Dr. Mills that sensations are not closely localized, and he agreed that we should speak of sensory areas, but did not believe we have sensory areas separate from the motor ones back in the post-central and parietal lobes or in the gyrus fornicatus. He does not accept Dr. Starr's view that the sensory centres are back of the fissure of Rolando, for from the evidence he had been able to collect there is just as much proof that the pre-central convolution has sensory functions as that the post-central one has.

Dr. Putnam thought Dr. Dana's closing sentence must be accepted as absolutely certain that the convolution in advance of the fissure of Rolando, which we ordinarily associate with the localized movements, has as much to do with sensation as convolutions anywhere else. In support of that fact he mentioned one case among many where Dr. Warren excised a minute piece of the cortex of a young man with epilepsy beginning in one hand—a piece a few millimetres in diameter—with the result of producing paresis of the hand, paralysis in the beginning, and also a disturbance of the sensibility of the whole hand. It seemed to him that showed in some way the function of sensibility is closely related to the same centres with the function of motion. What that relationship is, is a matter still calling for a great deal of study. His own view of the difficulty is that we are still decidedly lacking in a sufficiently adequate physiological or psychological conception of what we mean by these various terms. The function of sensibility must be very widely distributed. When any part of the body is touched or any motion takes place there, it calls immediately on various other functions to come into action. The motion of the

eyes must follow very rapidly on a sensation, because the individual touched must immediately know from what cause the touch arises, and the like ; so that close relationships must be established, and, as a matter of fact, we have every reason to think they are established, with all sorts of cerebral functions of various kinds. When we apply sensory stimulus we are applying what may perhaps be a very gross molecular disturbance of a nerve to the part touched, and then it impinges on some part of the brain primarily, and from there it must spread just as we know in the spinal cord a sensation will make its way from a minute portion of the substance of the cord that is left ; so in the case of the brain, if one channel is cut off it will make its way into a dozen other channels. An enormous tumor was removed, almost as large as an orange, which lay directly in the motor tract, and in the course of the operation Dr. Richardson put his finger down and thought he felt the falx and various recognizable bodies at the base of the brain, if not of the skull at any rate of the brain ; in short, it must be that the whole of the motor area was removed with a good part of the internal capsule. Nevertheless that patient still has a very considerable degree of sensation left, of course modified ; but in the first place contact gives rise to a painful distressing feeling, contact with the paralyzed parts : in the second place even a slight rubbing is felt, and the localization is still fairly good. Nevertheless he feels in a very high degree, so that although the removal of the motor convolution has affected the sensibility of the limb, it has not by any manner of means destroyed it. Nerves will stand a high degree of injury, sufficient to entirely destroy their motor functions, without interfering materially with their sensory functions. The same thing in the cord : a minute portion of it will convey centripetal impressions ; we have in our own power to make what may be tremendously powerful as compared with the little thrill corresponding to a motor impulse originating in a voluntary act ; so also in the brain, we know it takes a very extraordinary degree of mutilation of the brain to entirely destroy sensibility.

Although we must admit that the function of sensibility is closely related to the function of localized motion, we must admit that it is closely related to a great many other functions, and it remains to be seen whether, as in the case of the relation of the muscles of articulation to the function of speech, there is any centre which is highly specialized. He had in mind several cases where the sensory functions have been disturbed in connection with paresis of one hand, where he seemed to be able to detect a higher degree of loss of sensibility or impairment of sensibility on the side of the ulnar part of the hand than on the median portion.

Dr. Starr said we certainly have facts that Dr. Dana has stated that are indisputable, and those of us who are constantly seeing cases of cerebral surgery and exsecting cysts and portions of the cortex by clots that can be removed, are perfectly positive that a small limited area of the so-called motor zone does inevitably produce in almost every case more or less disturbance of sensation. He said he was completely mistaken in 1890, when he maintained that sensations were only to be referred behind the fissure of Rolando. He believed with Dr. Dana completely to-day, that there are sensations produced by small lesions anterior to the fissure of Rolando, and that the sensory area of the body corresponds exactly with its motor area, so far as we can determine clinically. He thought it would be a mistake to draw too broad a conclusion from these facts.

It is perfectly evident that the term diffusion of sensibility is a capital one, and our present anatomy shows why it is ; it is because these sensory fibres terminate in brush-like expansions, so that we must conceive of a sensory fibre as virtually terminating in a long region of the nervous system, in fact, almost throughout its entire length. Now, suppose that with the continued passage of sensations over these fibres diffusing themselves in general directions, habit opens the way in one direction rather than in another, that a sensation coming in might be diffused from the arm over the entire parietal arm-centre and also diffused over the motor-centre ; but inasmuch as we guide our movements by touch habitually, the result is that a greater passage is opened out over to the motor zone. Diffusion of the sensibility in various areas gives an explanation for the fact that a few cases are on record where we get sensations lost alone, and the vast majority of cases show that sensation and motion are lost together. We must abandon the idea of consciousness and conscious perception, and perhaps to some extent of conscious motion, being associated with particular cells. It is just as reasonable to believe it is associated with association fibre action, the combined activity of various areas of the brain, as it is with single cells, and he thought we will come down finally to the fact that a cell is to be regarded more as a trophic centre than as a motor or sensory.

Dr. Dercum said that the stand which had been taken enables us to explain certain other phenomena not alluded to here, namely, the fact that the cuneus atrophies in cases of blindness last for many years. Certain it is that we have no right to conclude from these facts that the cuneus only sees. It is probable it does other things. The various centres of the cortex, as we know them clinically and pathologically, are simply highways of ingress and egress to the general cortex. It gives us no right to say that this portion of the brain may do this special thing, and that portion that special thing. But general biological considerations also would negative the sharp differentiation of cells into special functions. Nerve protoplasm reacts to certain forces ; to say one cell would react to one mode of motion and another to another, is unphilosophical, and not borne out by general biological considerations.

Dr. Richardson said, in reference to the tumor Dr. Putnam spoke of, that so far as he knew there was no destruction of the motor areas except by pressure of the growth. The tumor was very large. It took up a very large portion of the left hemisphere. During the operation he touched the falx throughout a great deal of its extent, his finger passing through a very large opening through the crista galli to the tentorium. But, so far as he knew, there was no destruction of brain tissue by manipulation during the operation. The man is now doing very well.

Dr. Collins had recently had a case of cerebral surgery in which the development of sensory and motor defects were rather peculiar. The young man had his first attack of Jacksonian epilepsy in November, and the movements were contraction of the finger and thumb. When he saw him in March he had had three. In conjunction with Dr. Sachs, Dr. Gerster operated on the patient over the superficial cortical thumb-and-index-finger centre. As the patient bore the anæsthetic very badly, it was necessary to postpone the operation after the skull had been opened, that is, cutting into the cortex was deferred. That night he had an extremely severe attack, which had been preceded a short time by a very high temperature and loss of consciousness for a long time. The following morning he had paresis of the right upper extremity and loss of sensation, that is, loss of tactile sense, loss of sense of position, and loss of muscular sense in the right hand. Three or four days afterward the dressings were opened and a good deal of distention was found from effusion into the surrounding cellular tissue, but otherwise, where the operation had been done, it seemed very much like normal. Then a large part of the cortex was cut out. An old pachymeningitis was present, and the Nissl stain revealed degeneration of the cortical cell. He was put to bed and his hand tested for sensi-

bility that evening. The disturbances of sensation had all disappeared. These observations were made with extreme care.

Dr. Angell, of Rochester, corroborated Dr. Collins because he had a similar case. He made the prediction that there would be paralysis for five or six days at least, and to his surprise, when the boy recovered from ether two or three hours after operation, he tested him thoroughly and found sensory paralysis. Within twenty-four hours there was absolutely no sensory paralysis or sensory disturbance. He did not believe it possible to make an impression upon any centre of the brain closely related to another centre, without affecting temporarily that sensory centre. Whether this will explain the reason why we have a short paralysis of sensation when we remove the motor cortex or not is, of course, beyond our power yet to determine. It may be by cutting into the cortex that we affected the rootlets of the radicles from the sensory tract which we suppose reach over and produce this diffusion of sensation that has been referred to.

Dr. Prince, of Boston, said there is a third fact which Dr. Starr had left out of consideration, and that is the fact that, in many cases which have been referred to by other gentlemen, there has been no loss of sensation. These must be exceptional cases that must be taken into consideration in order to find a law. A great many could be mentioned. He referred to two which he thought were of great importance. Many will remember the case of Dr. Hall White, published in 1893, in which case he excised a certain portion of the cortex and with great care observed the effect on sensation, and although he had paralysis there was no loss of sensation. What seems to be a most crucial test was a case published a short time ago. In that case he first scooped out a piece of the brain equal in size to half an orange, leaving a hole two inches in depth, involving a very large portion of the upper part of the descending convolutions, caudate lobule, and some part of the parietal convolution. Before the operation there was hemi-anæsthesia with paralysis; after operation there was absolutely no loss of sensation whatsoever, tested in the most minute way. A case like that is a crucial case, and if the word centre has any meaning whatsoever it must mean a portion of brain the function of which is destroyed when taken away. These cases must be taken into consideration, and show that a large portion of the motor cortex can be destroyed without loss of sensation. Dr. Dana asks how to explain these other cases. That is another question. He did not know how to explain them. It is common to have injury of the corpus striatum with aphasia and sensory disturbances, and beginning with hemi-anopsia; hemi-anopsia is common with lesions of the corpus striatum, and yet no one localizes hemi-anopsia in the corpus striatum. Aphasia is common as a secondary disturbance with lesions in different parts, and yet we know where aphasia is located. We therefore must regard them in some way as secondary disturbances. In the case of the corpus striatum we can explain it by œdema, local congestion. It is possible it may be explained on some form of irritation of associated fibres, the effect of inhibition. Whatever the explanation, it seemed to him we must distinguish the facts and the logical deduction of those facts from any necessary explanation.

Dr. Putnam, of Boston, said no one would speak clinically or anatomically of the sense of hearing and comprehension of spoken words as located in the same part of the brain, but we know these two functions lean on each other internally so closely, that not only we get more or less aphasia from disturbance of the centre for hearing, but we also get to a less degree a great deal, as is also the case with sensory phenomena, of disturbance of centres, of comprehension in most forms of motor aphasia. In short, cerebral functions do not exist in themselves, they exist as related to other functions, and you cannot destroy one without more or less impairing others, although it may be only for a brief time.

The President added that the whole of our knowledge of the neuron goes to show the very pronounced dependence of the motor neuron upon the sensory neuron. In the primary neurons it has been clearly proven that the terminal processes of the axis cylinder of the sensory neuron are closely connected with the apical process of the motor neuron in the cord.

The development of the fibres in the cortex, in the brain itself, shows that the sensory tract passes distinctly upward toward the central convolution, the parietal region, rather than downward and inward toward the gyrus fornicatus where Ferrier some time ago located the sensory centres, and where Dr. Mills still has a leaning toward placing it. In other words, judging from all the analogies in the anatomy of the brain, the higher sensory neurons must either pass upward directly to connect by their axis cylinder processes with the cells of the body motor neuron, or there must be association tracts from these axis cylinders going up to the motor processes. We find no association tract passing up from the gyrus fornicatus to the central fissures, and furthermore, although Dr. Prince has just brought up the negative cases of lesion of the central convolution without injury to sensation, there have been in the past a very large number of so-called negative cases about the central convolution with absolutely no motor disturbances. Most of those with our increasing knowledge have been explained away, and ten negative cases do not afford as much evidence as one positive case. The positive cases of sensory disturbances following lesions behind and in front of the fissure of Rolando are increasing in number and become very conclusive. The positive cases of lesion in the neighborhood of the gyrus fornicatus are very few and far between.

Dr. Mills, in closing, claimed that this discussion confirmed the stand-points he had always taken. It seemed to him astounding that Dr. Dana and others here speak of the cases in which physiological or pathological lesion of the motor cortex as exceptionally producing alone motor symptoms. Everyone of us must admit the cases referred to by Dr. Starr and Dr. Dana, and by Dr. Putnam and Dr. Knapp's case, because we know they have been well studied and well recorded; that is, cases in which sensory phenomena of some sort have accompanied the motor phenomena in cases of destructive lesion of the pre-Rolandic cortex. We must admit, too, the two or three cases in which certain experiments upon the cortex in life have caused peculiar temporary disturbances of sensation at the time. The cases are as a hundred to one as the cases against the view that were collected by Brown-Séquard, as against the doctrine of crossed paralysis. These cases of sensory disturbance from strictly limited lesion of the motor cortex, cases in which the symptoms were motor alone instead of sensory, are as one hundred to one, and we do not think it longer worth while to collect these cases. He said positively that in a score of these cases with the greatest care the patients have been examined in life and the lesions located in death, and in cases of operation the greatest care had been taken in studying sensory phenomena, and those sensory phenomena had not been present. He mentioned two cases of his own, one in which Dr. Hearn cleanly excised a portion of the cortex and a portion right across and in front of the Rolandic fissure; another case in which Dr. Keene did the same thing, cleanly excising the cortex, and in which he studied with the greatest care, as soon as it was possible, the sensory phenomena, and in which these were not present, and in which the motor phenomena persisted day after day, and day after day changes were noted, until the patient was largely restored as regards motion and sensation not having disappeared at all. He did not think it worth while, therefore, to pit these cases which Dr. Dana had, with great skill and

labor, collected as an argument of great value against the very numerous cases which teach the other thing. However he must acknowledge the other cases. Have we no explanation for these cases? The explanations have been given here, some of them. He would suggest three or four explanations for these cases in which destructive lesions cephalad of the sensory area have given rise to sensory disturbance.

One explanation which may seem far fetched is that these cases are somewhat of the nature of the cases in which we have a sensory disturbance in hystero-traumatisms. Many times yesterday in the discussion they told us about hemi-anæsthesias and about segmental anæsthesia as result of a man being struck on the head, or leg, or trunk, and certainly the traumatism inflicted by the surgeon's knife, or by injury, or disease in acute cases, or by operation such as Dr. Dana refers to, is greater than that which we have in these other cases. Another explanation is that which he suggested in 1888, which grows out of these later researches on cortex anatomy. Undoubtedly every area of the cortex, visual, auditory, gustatory, sensory, etc., must be related and anatomically connected with the motor regions of the cortex. Now it is through the destruction of these terminals of the fillet radiations, whether they be continuous with the apical process of the pyramidal cells or simply constitute a field of conjunction, we have a separation between the motor and sensory areas, and at least temporary disturbances of sensation would very likely in many instances result. It is a great cortical sensory expanse in this sense, but there is one region in the brain in which these fillet radiations are placed between the cortex, and which for the surgeon's and physician's purpose should be regarded as the sensory region. It is next to the motor region, and between the motor and great sensory region. It has a separation, and one which I believe is practical for our purposes.

The remarks made by Dr. Starr he thought were on the whole confirmatory of what he had stated. It would seem, therefore, that the weight of argument and the weight of the evidence advanced here is still in favor of the localizations to which he had always clung, and which were believed in by Charcot, Ferrier, and others. He had never claimed the gyrus fornicatus was the sole region of common sensibility in the cortex of the brain. His own position always has been that the sensory cortex proper includes at least a portion of the gyrus fornicatus, quadrate lobule, posterior parietal convolutions, and the arguments he advances must stand for the motor region and not for a part of it.

Dr. Dana asked if Dr. Mills would tell us specifically whether he denies that the central convolutions have any sensory function, if he absolutely excludes sensory function from the central convolution.

Dr. Mills replied that for our purposes and for our practical idea of a centre or area, he believed the central convolution or convolution cephalad of the central fissure had no sensory function; he believed the posterior central convolution and the posterior parietal and the region he had named perhaps take part in sensory phenomena, that is, the sensory region posterior of the central fissure.

Tumor of Cerebellum with Autopsy.—This was the title of a paper by Dr. E. D. Fisher, of New York. The interesting feature of the case was the absence of any symptoms that could be directly referred to the cerebellum. There was no inco-ordination, nor any staggering in the gait. The pain was situated principally over the right orbit.

The only well-defined cranial lesion was that of the eighth nerve on the right side, there being absolute deafness. There was possibly a slight involvement of the seventh nerve on the right side, and the patient said she had complete loss of smell. The general symptoms of a cerebral tumor, *i.e.*, headache, convulsion, and optic neuritis, were present. A lesion at the base of the brain was suggested by the cranial nerve lesion, with involvement of the cerebellum; the absence, however, of cerebellar symptoms, and the localization of the pain so definitely over the right orbit, led to an exploratory operation in that situation. The tumor was not found at the time, but there was a complete relief from the pain and the convulsions until the time of death, eleven weeks later, which was caused by a septic basilar meningitis. Autopsy revealed a glioma involving the right cerebellar hemisphere. The operation was by the bone-flap method of procedure.

Cases of Brain Tumor.—Dr. Preston, of Baltimore, related three cases of tumor of the brain with autopsy. The first case was that of a boy aged thirteen. For a year he had what looked like ordinary epileptic attacks, which were very much lessened by the bromides. Then he suddenly developed diplopia with some neuro-retinitis. Vision was greatly reduced, and there was at first left lateral achromatopsia, and afterward left hemi-anopsia. Gradually he lost entirely both sight and hearing. The reflexes, both superficial and deep, were lost. He complained of most intense headache, and there was gradual failure of mental power. The autopsy revealed a large tumor involving the entire right temporal lobe; the occipital lobe was softened and broken down, but the cortical portion of the occipital lobe was not involved. The tumor was a sarcoma. The second case was interesting from the fact that the tumor, a small papilloma not larger than a partridge egg, buried itself in the right superior occipital convolution, producing intense headache, with double optic neuritis. The third case showed a large sarcomatous tumor involving the temporal lobe all except the first convolution, the greater part of the occipital lobe, and the lateral lobe of the cerebellum. The symptoms were not very well marked except headache and mental disturbance. It was interesting to note that the first temporal convolution was not involved, though the rest of the lobe was virtually destroyed, and in accordance with our accepted views concerning the auditory centres, there was deafness.

Brain Tumor.—This was the presentation of a specimen by Dr. G. L. Walton, of Boston. The main interest was the question whether operation might have proved successful. The patient was fifty-three years of age, and complained of frontal headache only two months before his death. Attacks of vertigo, loss of speech, and several general convulsions preceded and followed. Aphasia, agraphia, right hemiplegia, and right hemi-anopsia were present. Double optic neuritis and loss of superficial reflexes on the right. The tumor occupied the angle between the Rolandic and Sylvian fissures. Extension forward under the healthy cortex reached beyond the transverse frontal sulcus. It was fairly well defined but with no distinct capsule. The centre was necrotic. The symptoms suggested so extensive infiltration that operation was considered to offer small hope, but the extension backward was not so great as the hemi-anopsia would indicate, a fact which, together with recently published cases of removal of large infiltrating gliomata, would lead, perhaps, to a somewhat more hopeful prognosis in another case of this nature.

The three preceding papers were discussed together.

Dr. Starr referred to a case of infiltrating glioma in the arm area of the motor zone. Symptoms developed in the course of a year. Headache, optic neuritis, spasm of right hand and arm. Later paresis and loss of sensation. Operation by curved bone-flap. Glioma very extensive and very vascular. It was impossible to remove it safely. Death within a few hours. He mentioned a case of suspected tumor of corpora quadrigemina. A flap of bone was removed from parietal region and attempt to puncture ventricles was unsuccessful. No relief of pain. He concluded that operation under such conditions was useless. He agreed with Dr. Fisher that the position of the pain is of no value in localization.

Dr. Dana said that the use of the chisel upon children and infants is a bad method of operation. He recommended the use of the improved revolving electrical saw, as used by Dr. Powell, of New York.

Dr. George W. Jacoby, of New York, had witnessed two operations upon adults in which the electrical saw was used. He considered the method objectionable, as there was more hemorrhage and a wedging of the saw interfered with the operation. He spoke favorably of Quincke's lumbar puncture for relief of intracranial pressure.

Dr. Dercum spoke in favor of a perpendicular burr worked by a dental engine.

Dr. Collins had seen a case where after each series of blows from the mallet and chisel the pulse fell from 60 or 70 to 35 or 40.

Dr. G. M. Hammond had witnessed one operation with the electrical saw upon an adult, and many upon children. The saw as now used has a greater electromotive force to operate it than formerly, and this obviates the earlier difficulties as mentioned by Dr. Jacoby.

Dr. Dercum had noticed the same symptoms following the use of the chisel as described by Dr. Collins.

Injury of the Angular Gyrus from Fracture of the Skull.—This was a report of a case by Dr. C. Eugene Riggs, of St. Paul.

Hereditary Chorea with Autopsy.—This was the title of a paper by Dr. Charles L. Dana, New York.

Dr. Mills looked upon the case as very important. It suggested the true explanation of a large class of cases (such as Friedreich's ataxia, hereditary chorea, spastic paralysis), that these are teratological.

Insanity and Phthisis, their Transmutation, Concurrence, and Coexistence.—Dr. H. A. Tomlinson, of St. Peter, read a paper with the above title. He considered that phthisis and insanity are equally potent factors in the production of brain instability.

The preponderance of degeneration among those having an heredity of phthisis is significant, as indicative of the influence of phthisis in one generation, in determining a defective nervous system in the next, and his tables also indicated that the more direct the heredity, the greater is the probability of transmutation.

Disease processes which are constitutional or diathetic attack primarily one or other form of tissue, with the result of progressive degeneration and disintegration if the tissue be epithelial. However, if the connective tissue is the seat of a disease process it either increases rapidly in amount, and remains permanently increased, or undergoes liquefaction.

The most common form of degeneration among the insane is the connective-tissue type, or the premature and excessive manifestation of the changes which ordinarily occur in senility.

The preponderance of imperfectly developed connective tissue in one generation implies the excessive development of functional tissue in the next, thus accounting for the transmutation of disease tendency. These changes are abundantly illustrated in the tuberculous and defective children of neurotic or syphilitic parents.

Third Day, Friday, June 7, 1895.

The Diagnosis of Pachymeningitis Interna Hemorrhagica.—Dr. William N. Bullard, of Boston, read this paper. He considered the pathology of this affection as yet unsettled, though he believed the weight of evidence to be in favor of a non-inflammatory origin. There are several forms of subdural hemorrhage, but what follows applies only to the apparently spontaneous, non-traumatic affection occurring in adults. The points of differential diagnosis between this condition and other forms of intra-cranial hemorrhage are: 1. The subdural hemorrhage is peculiarly common in paralytic dements and in the chronic insane, and not rare in chronic alcoholics. 2. The onset is often more gradual than in ordinary intra-cranial hemorrhage, and the irritative stage lasts unusually long. 3. The symptoms of irritation are prominent. General epileptiform convulsions and localized convulsive movements are apt to occur. 4. The peculiar rigidity occurring in one limb in connection with symptoms of hemorrhage, and where no affection like tubercular meningitis exists, is very significant. The treatment in this condition is removal of the clot. In all more serious cases this should be done as soon as the disease is recognized. The author reported a case in which operation was performed and the clot removed, although too late to save the life of the patient.

Dr. Tomlinson thought the term pachymeningitis was a misnomer. The primary condition was non-inflammatory. In syphilitic cases there are no signs of active inflammation, but changes in the blood-vessels.

Dr. Fisher believed that the blood comes from newly formed vessels which have resulted from inflammation, and asked what the special indications were for operative interference.

Dr. Bullard answered that operation was indicated where symptoms of pressure existed. The question as to the origin of the disease remains *sub judice*.

Tabes and Multiple Sclerosis.—Dr. E. W. Taylor, of Boston, showed a patient suffering with the unusual complication of tabes dorsalis and multiple sclerosis. Probable syphilitic infection twenty years ago. The patient first noticed a tumor of the hands fourteen years ago, followed by pain of a lancinating character in the legs, associated with general muscular weakness. Gradual increase of these symptoms, with occasional paræsthesia of the legs. Girdle sensation and difficulty in micturition. Loss of knee-jerk, Argyle Robertson pupil, lancinating pains, disturbances of sensibility, making the diagnosis of tabes dorsalis unquestioned. In addition, slight nystagmus, spasm of posterior thigh muscles, muscular weakness, hesitating speech, and absolutely characteristic intention tremor, which masks what little ataxia he has.

Dr. Prince then presented microscopical specimens from a case of cerebro-spinal syphilis.

Pathology and Morbid Anatomy of Amyotrophic Lateral Sclerosis.—This was the report of two cases with autopsy by Dr. Joseph Collins, of New York.

After referring to the moderately constant clinical picture of amyotrophic lateral sclerosis, and the variable pathological conditions on which they have been found to be dependent, he referred to the fact that the number of cases in the literature which were well substantiated by autopsy were fewer in number than one might be inclined to think. Reference was also made to the different views held by the followers of Charcot and Erb on one hand, the Gowers, Leyden, and others as to whether the disease is primarily of the pyramids with a secondary involvement of the anterior horns, or whether it is but a variation from the common form of progressive muscular atrophy. The first case was a male, thirty-three years of age. The autopsy showed atrophy of the ganglionic cells throughout the cord; in the cervical and dorsal regions, evidences of excessive vascularity, in the shape of large thickened blood-vessels, especially in the gray matter and spaces from which vessels have dropped. In the cervical cord, corresponding to the place of apparent softening in the recent state, was found great disorganization of the ground substance of the anterior horns. In the medulla, degeneration of the nucleus throughout the entire extent with the exception of the extreme caudad end. Slight degeneration in the tenth and common vago-accessorio-glosso-pharyngeal nucleus. No degeneration of the pyramids of the medulla. Root of the twelfth nerve small and delicate.

Case II. was a male, forty-eight years of age. A piece of cord from the cervical region placed in alcohol and cultures made from it revealed the presence of the tubercle bacillus in considerable numbers. In cervical region, degeneration in the crossed and direct pyramidal tracts with almost complete destruction of the anterior horns could be made out. In the dorsal region there was sclerosis of crossed pyramidal tracts, slight sclerosis of ascending cerebellar tracts, diffusedly distributed dilated blood-vessels, some with very much thickened walls. Extensive atrophy of cells of anterior horns. Same degeneration in lumbar and sacral regions as in dorsal, but in lesser degree. In medulla atrophic changes in the nucleus of the twelfth nerve. Hemorrhage of ancient date in dorsal region.

The findings in these two cases were then analyzed and commented on in detail.

Peroneal Muscular Atrophy with Autopsy.—Dr. William C. Krauss, of Buffalo, read the history of a case of muscular atrophy in a man seventy-eight years of age, who at the age of eighteen began to notice a weakness of the leg muscles. This weakness was accompanied by atrophy in the peroneal and hamstring muscles of both legs, and extended to the muscles of the thigh, the left thigh being much more affected than the right. Double club-foot of the pes-varus variety resulted and also a double genu-valgum. The tendon reflexes were absent on the left side, also on the right with exception of the patellar tendon. Fibrillary contractions and sensory disturbances were entirely wanting. There was present a lordosis and scoliosis of the lumbo-sacral region. The muscles of the upper extremities were unaffected. The patient gave no history of any infantile disease, no poliomyelitis, and ascribes the affection as the result of an accident. Patient died of uræmia. Microscopic examination of the spinal cord revealed atrophy of the anterior horns, especially on the left side, extending from the caudal part of the thoracic region to the conus medullaris. The multipolar cells of the antero-lateral group are visibly affected, resulting in their disappearance, atrophy, or degeneration, while the median group is less affected; the left side is much more affected than the right. The white matter is somewhat sclerosed, particularly in the antero-lateral and posterior columns, but not more than the age of the patient would warrant.

Dr. Collins remarked that unless Dr. Krauss establishes that this was not a case of chronic anterior poliomyelitis, then it should not be accepted as one of the peroneal type of muscular atrophy.

Writers' Cramp.—Dr. J. W. Putnam, of Buffalo, reported a case of writers' cramp in a telegrapher. The man had previously had telegraphers' paralysis of wrist, later the symptoms increased to such an extent that the mere suggestion of writing or thought of writing would bring on the spasm. The spasm, in addition to the arm muscles, involved the trapezius and sterno-cleido-mastoid of the left side. The result was that when attempting to write the head would twist around to such an extent that he was unable to see the paper. The patient was treated by hypnotism and deep muscular injections of atropine. Result after two months was complete recovery.

Dr. Riggs had seen a similar case, but the trapezius was not involved. Much relief was obtained by the use of hyoscine hydrobromate.

Dr. Leszynsky asked whether the favorable result was due to hypnotism or atropine.

Dr. Putnam replied that he attributed the recovery to suggestion through hypnotism.

Dr. Smith Baker said that he had come to consider the associated contractions (those of the shoulder, head, etc.) as natural outcomes of the habitual attitude assumed by everyone whenever they intend to do any particular thing whatever. They may be designated as associated intention contractions. The origin of these undoubtedly dates back to the time of either learning to write, or of some position incidentally assumed for comfort, or other favoring result. The cure of them may come about through any means whereby the associations are broken up. Possibly writers' cramp itself is most frequently of purely psychical origin, and so rest or hypnotism, or any other sufficient psychical impression kept up long enough, will result in recovery.

Auto-mimesis.—This was the title of a paper by Dr. Smith Baker, of Utica.

He defined auto-mimesis as the process whereby impressions from the outside world, or conceptions arising in the mind, are first set as copy-models, and then automatically reproduced more or less indefinitely, until results detrimental or otherwise are attained. As usually considered, imitation means the reproduction of features found in other individuals. Auto-mimesis, or self-mimicry, means the serial reproduction of characteristics dominant at some particular time in one's own mind. How such a copy-model first comes to be set and subsequently followed is often a mystery. But a pain, or shock, or word, or muscular tension, or unusual idea, or any incidental experience, undoubtedly affords the requisite suggestion—imitative impulse. This is often seen in the development of hysteria, neurasthenia, melancholia, insistent ideation, and allied states and tendencies, while evidence is accumulating to show that the succeeding auto-mimesis series is a quite natural outcome of such an imitative impression. Cases illustrating auto-mimetic development of disease were given, and the conclusion reached that possibly in this way there have been opened up points of view, both as to etiology and therapy, which are of value to neurologists.

Dr. Ralph L. Parsons, of Sing Sing, presented drawings and photographs illustrative of a new system of baths inaugurated at his institution.

Obstetrical Paralysis.—This was a paper by Dr. G. L. Walton, of Boston. He said Carter assumes a stretching of the brachial plexus at a spot above the origin of the supra-scapular nerve. This does not account for the escape of the branch to the pectoralis major, which passes off immediately below. The same difficulty presents itself in Oppenheim's theory of pressure against the clavicle. The reader suggested that the supra-scapular is probably bruised independently against the supra-scapular notch or spine of the scapula, while the plexus below is bruised against the clavicle. The branch to the pectoralis major escapes through having no bony point of fixation. Probably rotation of the face away from the shoulder, which is caught at the brim of the pelvis, aids the stretching, as well as the drawing away of the head already described in this connection.

Discussed by Drs. Starr, Leszynsky, and the President.

The following papers were read by title:

"Home Treatment of Insanity," by H. M. Bannister, M.D., of Chicago; "The Dual Action of the Brain," by Samuel B. Lyon, M.D., of Bloomingdale; "An Operative Procedure for the Relief of Basilar Meningitis Limited to the Posterior Fossa," by J. T. Eskridge, of Denver; "Fissural Studies of the Brain of Two Philosophers," by Professor Burt G. Wilder, M.D., of Ithaca; "The Association of Tabes and Paretic Dementia," by Theodore M. Diller, M.D., of Pittsburg; "Must Acute Paranoia be Admitted into our Nomenclature," by William Noyes, M.D., of Foxboro'; "The Conservative Value of the Play Impulse," by Irving C. Rosse, M.D., of Washington; "Telegraphers' Paralysis," by James Hendrie Lloyd, of Philadelphia; "Case of Multiple Neuritis in an Infant," by Graeme M. Hammond, M.D., of New York; "Pseudo-neurasthenia," by Morton Prince, M.D., of Boston.

Election of Members.—The following named gentlemen were elected to active membership: Dr. Hugh F. Patrick, of Chicago; Dr. Edward Wyllys Taylor,

of Boston; Dr. Leopold Stieglitz, of New York; Dr. John Jenks Thomas, of Boston; Dr. H. L. Worcester, of Danvers; Dr. B. Onuf, of Brooklyn, N. Y.

Honorary Members.—Dr. S. Weir Mitchell, of Philadelphia; Dr. Camillo Golgi; Dr. L. Edinger, of Frankfort; Dr. Ramon y Cajal, of Barcelona; Dr. Dejerino, of Paris.

Election of Officers.—The officers elected for the ensuing year were: *President*, Dr. F. X. Dercum, of Philadelphia: *Vice-Presidents*, Dr. George J. Preston, of Baltimore, and Dr. C. E. Riggs, of St. Paul; *Secretary and Treasurer*, Dr. G. M. Hammond, of New York.

Clinical Department.

PERMANGANATE OF POTASSIUM IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

By LOUIS BARKAN, M.D.,

BROOKLYN, N. Y.

In 1885 I employed this drug with most gratifying success in two cases of "butcher poisoning." In both cases a quite slight cut on the hand had produced several great swellings along the hand, fore and upper arm, and there was a copious discharge of pus. Washing the wounds with a solution of permanganate of potassium and covering them freely with iodoform produced little effect. On the eighth day in one patient, and the tenth day in the other, chills occurred. I then began the use of potassium permanganate, giving a drinking-glass of a light red solution three times a day. The next day there was a very considerable change for the better, shivering had ceased, appetite and sleep had come back, and I was justified in considering both patients out of danger. This convinced me that permanganate of potassium is not only good for snake but for "butcher poisoning" too. I hope it is equally good for poisoning derived from dissections.

In March, 1893, I took I. B——, a phthisical boy of sixteen years, to Lakewood. I had treated him for two years. The boy had cavities on both sides and was so reduced in health and strength that in order to come to the ferry he only could use the horse-cars, being unable to climb the stairs of the elevated railroad or to stand the shaking of a carriage. In Lakewood we stayed at a farm-house, standing by itself on a hill, with well-ventilated rooms. In the first five days no improvement could be observed. The patient continued feverish, coughing, weak, rather sleepless, and perspiring at night, the usual means having failed to help; creosote was given, but after being used for several days was refused by the patient. I gave him then a drinking-glass of a light red solution of permanganate of potassium half an hour before breakfast, and a solution of ten grains of salicylic acid before going to bed on eight succeeding days. I consider the latter far superior to quinine in tuberculosis, as it not only does not interfere with digestion, but rather promotes it.

A couple of days later the patient felt much better and could go out into the open air without feeling chilly. Eight days after commencing this treatment the patient enjoyed his meals—ate three eggs for breakfast, slept well, did not sweat any more, and was in excellent spirits. On the fourteenth day of his stay in Lakewood he was able to escort me to the depot and to walk back without discomfort—a distance of a mile and a half. The pulmonary cavities were then almost healed, his appearance and face looked surprisingly well.

In two other cases of less grave tuberculosis I experienced the same good effect with the same treatment. The fourth case was a combination of influenza with symptoms of tuberculosis. An hour and a half after breakfast the patient, C. B——, took a small drinking-glass of a dark red solution of permanganate of potassium, five times a week, and a solution of ten grains of salicylic acid before going to bed. The patient recovered quickly, but on account of relapses produced by her mode of living, I had to repeat this treatment several times, which always was beneficial to her.

NEW TREATMENT FOR FRACTURE OF THE PATELLA.

By T. E. SCHUMPERT, M.D.,

SURGEON TO THE CHARITY HOSPITAL, SHREVEPORT, LA.

I THINK I cannot better demonstrate the treatment which I am about to recommend than to cite my first case.

Mary B——, aged twenty-five, negro, farm-hand. Admitted December 27, 1895. Diagnosis: Fracture of both patellæ. This patient was brought into the hospital supported by a man under each arm, unable to walk or stand without assistance. About the first of May, 1894, while walking with a child in her arms, she stumbled and fell backward, and was unable to again resume the erect posture until aided. The physician who was called in dressed a fracture of the left patella, by what method I am not aware, but the patient was permitted to walk after the first week, with one crutch and no dressing save a dry roller bandage applied about the knee. This crutch she continued to use until December 24th, when, while stepping from the door to the ground, a distance of about eighteen inches, with the sound limb in advance, the knee gave way and she had a second fall. Three days later I saw her at the hospital, with a recent fracture of the right knee and a fracture with ligamentous union of the left. The fragments of the old fracture were separated three inches. Having procured from a hardware-store two slender ordinary screws, one-half inch in length, we were ready to proceed with the operation. I first boiled the screws a half-hour, and then placed them in pure carbolic acid for another half hour, then in a carbolized solution with the instruments, to remain until used.

After the usual preparation on the previous day, with an antiseptic dressing applied about the leg, on the day of the operation, taking every antiseptic precaution, I selected the limb with the old fracture to employ the treatment which I am about to detail, deeming this the most unfavorable for a good result. The leg having been flexed on the thigh to a little less than right angles, I made a transverse incision through the skin between the fragments, extending from the outer to the inner condyle. I then dissected back the integument, laying bare the fragment both above and below, as well as the intervening ligament. The ligament was next removed, and the edges of the bone well denuded. Then with a drill I slightly punctured each fragment about its middle, and with an ordinary screw-driver inserted a screw in each fragment until within one turn of its full length. The leg was now extended, and after having my assistants press the quadriceps extensor from above downward I was able to bring the fragments of bone into apposition, and with a silver wire applied around the screws by the figure-of-eight method, to keep them in contact. The integument was next brought over and sutured, and the leg dressed by full extension with a suitable splint beneath and a dry roller bandage applied about the thigh from above downward, also one applied about the leg, with a third figure-of-eight bandage applied tightly about the knee, the latter bandage having been disturbed but once during eight weeks. I prefer the figure-of-eight to the all-round method of applying the wire, because it prevents to any very great extent the ducking of the heads of the screws, which could be distinctly felt beneath the skin. The figure-of-eight bandage depresses the ligamentum patella and quadriceps extensor tendon and brings the fragments together through-

out its entire depth. My idea was to inject cocaine over the head of each screw after the fracture had healed, and by unscrewing to withdraw them, but on attempting this I found that they were encysted and it could not be done. I think in my next case I shall not insert them so deeply. The result secured was perfect, with no impairment in motion of the joint. The fracture of the right leg, though a much more favorable case, was treated by another method, and the result was not nearly so good.

ACCIDENTS TO THE EYE WHILE CHOPPING WITH A HOE.

By W. L. BULLARD, M.D.,

COLUMBUS, GA.

In the South, at this season of the year, when the farmers are chopping cotton, and especially so in sections of country where rocks or stone are found, the ophthalmologist is frequently consulted by patients who come, exclaiming, "Doctor, I wish that you would examine my eye; I think that I have a chip of stone in it." The experienced eye surgeon knows at once that the foreign body is a piece of steel from the hoe, and its sequel depends largely upon the force with which the eye is struck and the length of time intervening between the accident and the time of the consultation. A *résumé* of the following cases, described as succinctly as possible, will designate such to be true.

Case I.—Miss A——, aged fourteen, near Griffin, Ga., was referred to me in May, 1886. She came with the idea that "a piece of rock had struck her in the eye while chopping cotton." Macroscopically, a piece of steel from the hoe could be seen piercing the iris, midway between the pupillary zone and the periphery. Its track could be seen where it perforated the cornea. Accident happened two days before. Eye very sensitive to light, and showed evidence of no little inflammatory action. Advised an operation, which was consented to. Cornea, after cocainization, incised, and with iris forceps the foreign body grasped, including the iris, drawn out, and removed as in simple iridectomy, and the wound treated in the same way, with perfect results.

Case II.—Mr. E——, aged thirty, Howards, Ga. Consulted me in May, 1890, complaining as above. The steel, which was about the size of a pin-head, could be seen resting on the iris, and an incision was made in the cornea and the piece removed with forceps, after which wound treated in the usual way, with perfect results.

Case III.—Mr. G——, aged thirty-five, Hamilton, Ga. Consulted me in May, 1892, with the same tale of woe as Cases I. and II. The chip of steel could be seen embedded in the iris. An iridectomy was performed, together with the extraction of the foreign body. Wound treated as that after simple iridectomy, with perfect result.

Case IV.—Mrs. S——, Dadeville, Ala. Referred to me in May, 1894, by Dr. B——. The bit of steel could be seen embedded in the iris; iridectomy performed, and a piece of steel removed; wound dressed as usual, and patient sent directly home. Wound did not heal as advised, and Dr. B——, the family physician, was consulted, and another piece of steel extracted from the corneal wound (this information furnished by the patient's husband), which healed without any further trouble.

Case V.—Mr. S——, aged fifty, Talbotton, Ga. Was referred to me in June, 1894, by his family physician, a few days after the accident. Patient thought "that a piece of rock had hit him in the eye, but felt sure that he had gotten it out." A glance at the eye convinced me that irido-cyclitis had set in, and I advised enucleation, after which the ball was cut open, and the piece of steel found in the vitreous.

Case VI.—Mr. I——, aged nineteen, Lee County, Ala. Was brought by his father to my office six days ago, telling me that "his boy had a rock in his eye." The accident occurred three days previously, and the pain was most excruciating, with constant vomiting. Panophthalmitis had made considerable headway, and enucleation was advised, and at once performed, which gave immediate relief. The chip of steel was found in the vitreous.

Case VII.—Mrs. D——, aged forty-five, Mountain Hill, Ga. Brought to my office three days ago by her husband, who informed me that "his wife while chopping with a hoe struck a rock, and a piece of it struck her in the eye." Directly after the accident Mrs. D—— was seen by the family physician, who advised that I should see the case, which was done in nine hours after the accident. The piece of steel could be seen lying on the lens, between it and the iris. An incision was made in the cornea, as in iridectomy, and with a pair of iris forceps the offending member was extracted, to my delight and the patient's joy, on the first attempt. The iris prolapsed but was replaced, a solution of pilocarpine used, and at this writing—three days afterward—the indications are good for a perfect recovery.

I could add other cases, but these are enough to convince us that when we see in the press—as we oftentimes do—"That Mr. A—— or Master B—— has lost an eye by a chip of stone," it is a fragment of steel from the hoe that should be held responsible for the damage.

1408 Third Avenue, May 14, 1895.

OPERATION FOR GUNSHOT WOUND OF THE ABDOMEN.

By JOSEPH N. STUDY, M.D.,

CAMBRIDGE CITY, IND.

On the morning of October 25, 1894, J. W——, aged sixty-five, American, after shooting his infant child shot himself, the weapon used being a 22-calibre repeating pistol. The bullet penetrated his abdomen one inch above, and one and one-half inch to the left of, the umbilicus. Within a few minutes after the injury, his symptoms became bad, and to all appearances severe internal hemorrhage had occurred. After three hours it was thought his symptoms had slightly improved. Twenty-five hours after the injury permission was given to open the abdomen. The skin over the abdomen was well cleansed, and the man being etherized I proceeded to do abdominal section, assisted by Dr. Boyd, of this place. An effort was made to do an aseptic operation. A median incision was made, at first four inches, increased to six inches, the upper point of the incision being two inches above the entrance of the bullet.

The abdominal cavity was well filled with blood and traces of fæces were observed. It was found that the bullet, after penetrating the walls of the abdomen, had pursued a course downward and backward, and had done little injury until coming in contact with the inferior mesenteric vein, wounding this vessel causing the hemorrhage. The bullet next penetrated the descending colon immediately above the sigmoid flexure, passing through the intestine antero-posteriorly, making two openings from which some fæces were seen to pass.

The ball was not found, but was supposed to have embedded itself in the deep muscles. The bleeding vessel was ligated with catgut, the two openings in the intestine closed by Lembert sutures, the abdominal cavity cleansed carefully, the abdominal incision sutured, and drainage-tube inserted at lower end of incision.

The operation lasted forty minutes. The man was placed in bed with warm water bottles to his body and extremities. Hypodermic injections of ether were given, and strychnine, one-sixtieth grain, every half hour till four doses were given, then every one to two hours. Death occurred seven hours after the operation.

Two points were well shown in this case. One, the man would most certainly have died without the operation. The other, operations for such injuries should be done soon after their occurrence.

A PEANUT IMPACTED IN THE LEFT BRONCHUS.

By W. MOSER, M.D.,
BROOKLYN, N. Y.,
PATHOLOGIST TO ST. CATHARINE'S AND THE BROOKLYN THROAT HOSPITAL.

The pod of the arachis hypogæa contains a seed which, as we all know, is so designed by nature as to be readily divided into two halves.

I recently performed an autopsy at St. Catharine's Hospital on a child about two years of age, in which one-half of the nut was found impacted in the left bronchus, completely occluding the opening from the trachea at the point of bifurcation. The nut was firmly impacted at this site, and excited ulceration of the surrounding tissue.

The common result of foreign bodies which enter the trachea is that they are arrested, not in the left bronchus as in this case, but in the right. The right bronchus being wider and more horizontal than the left probably explains this tendency. Goodall states that the septum is a little to the left of the median line where the trachea divides, and this, too, might explain why the right bronchus is more frequently the seat of foreign bodies than the left (Bryant). When a foreign body becomes impacted in the larynx death is caused by spasm of the glottis or by œdema. But when either bronchus becomes obstructed by some foreign body the danger lies in broncho-pneumonia. This may come on rapidly or slowly and may affect only one lung, or, as in the case in question, both lower lobes were consolidated within two weeks. Tracheotomy must be performed early in these cases, as the secondary pneumonia renders the prognosis bad.

The moral to be drawn from this case is that infants should not be fed on the *pistache de terre*, which is light, smooth, and slippery, and may easily, when the glottis is open, pass into either bronchus. Parents feeding their children on peanuts at the circus should not let the child laugh too heartily, lest the accident occur.

158 Ross Street.

Disinfection of Localities.—MM. Laveran and Vaillard announce that from their experiments they believe the best method of disinfecting the walls of habitations consists of first washing the walls with soapsuds, then with a five per cent. carbolic-acid solution or to two to one thousand of sublimate, acidulated. In all localities which are exposed to frequent soiling—hospitals, barracks, schools, hotel-rooms, etc., the walls should be of impermeable material, easy to clean and disinfect. If sprays are used the liquid should be made to stream along the walls, but in this way the disinfection is often imperfect. The carbolic solution is preferable to the sublimate, it seems.—*Journal of the American Medical Association.*

Bismarck's Head has recently been measured by a sculptor. It is 212 mm. in length and 170 mm. in breadth, or $8\frac{1}{3}$ by $6\frac{2}{3}$ inches.

New Instruments.

A CHLOROFORM-DROPPER.

By C. HOLTZCLAW, M.D.,
CHATTANOOGA, TENN.

Appreciating the efficacy of the drop method in the administration of chloroform, and the impracticability of all other chloroform droppers now in use, I have adopted the old chemical drop-bottle for this purpose. It is a ground-glass stoppered bottle, on the rim or flange of which a lip is blown. From this lip there extends downward a small groove on the inside, about half the length of the neck. On the opposite side, about the middle of the neck, there is a small hole for the admission of air.

In the ground-glass stopper there are, on opposite sides, two grooves extending about half the length of the stopper. When wanted for use, the stopper is turned so that its grooves come in apposition with the air-hole on one side, and with the grooves in the neck on the other. This adjustment can be so regulated as to permit a stream to flow, or only a drop every two or three seconds. When not in use, the stopper is turned half-way around, removing the grooves from the air-hole and groove in the neck, thus completely closing these apertures. The bottle then can be carried in pocket or satchel, without danger of leakage or evaporation. It is, at once, a supply bottle and dropper combined.

I suggest its general adoption for the purpose, as being compact, practical, easily manipulated, and not liable to get out of order. The bottle can be made of any size, and the danger of breaking can be obviated by enclosing in a corrugated, drawn-metal case.

LIGATURE-CARRIER FOR THE PEDICLE OF ABDOMINAL TUMORS.

By AUGUSTIN H. GOELET, M.D.,
NEW YORK.

The accompanying illustration represents a ligature-carrier for the pedicle of abdominal tumors which was shown at a meeting of the New York Obstetrical Society, May 15, 1894. It possesses some advantages over similar instruments now in use, which can perhaps be better explained by comparison with the well-known ligature-carrier of Dr. Cleveland. That otherwise very admirable instrument does not hold the ligature firmly, consequently the latter frequently slips out of its grasp, necessitating reinsertion. The instrument shown in the

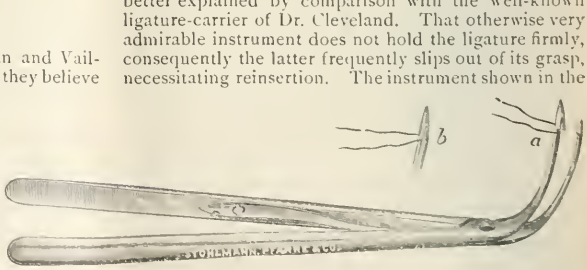

illustration has a projecting shoulder on the inner surface of each blade, near the point, each overlapping the other when closed (see *a*, in the figure), which renders slipping of the ligature impossible. In addition to this improvement the handles are made straight, like the handle of an ordinary needle-holder, instead of a scissors-handle. This makes it possible to grasp and use the instrument more quickly. A spring separates the

two arms and at the same time the blades, when the grasp of the hand upon the handle is relaxed. The blades are joined by a new lock, which permits them to be readily separated for cleansing, and the instrument can be made perfectly aseptic.

In using the instrument grasp it firmly in the right hand, thus closing the blades, transfix the pedicle, then relax the hand-pressure, thus separating the blades, insert the ligature between them, compress the handle and withdraw the instrument and ligature through the pedicle.

A NEW NEEDLE.

By JAMES SPENCER BROWN, M.D.,

ATTENDING SURGEON TO MOUNTAINSIDE HOSPITAL, MONTCLAIR, N. J.

While not desiring to add to the now too numerous instruments used by the surgeon, the cut below represents a needle which has been used by the author and found to combine many desirable features, when rapidity of work and thorough asepsis are demanded. I am therefore tempted to present it to the profession.

The method of its use is as follows: The needle is sterilized with the other instruments about to be used. The surgeon then takes a spool of either sterilized catgut or silk, as desired, removes the steel guy from the handle, and runs the spool over the needle down to the handle, replaces the guy, threads the needle and places it in alcohol with the other needles, etc.

The operator uses it as any Peasley needle, but instead of being compelled to thread the needle each time he needs but to take hold of the free end of the suture material with a pair of catch-forceps and draw the needle back. The spool unrolls and a suture is left in position. The suture is then cut the desired length and the needle is again ready for the next suture.

The desirable features of this over the ordinary Peasley needle are that all handling of the suture material is done away with. No time is lost in threading numerous needles—consequently rapidity of work.

The author has found the needle of especial advantage in plastic work and in placing in position the many skin sutures after cœliotomy.

I desire to extend my thanks to Messrs. George Tiemann & Co., of New York, for carrying out my ideas.

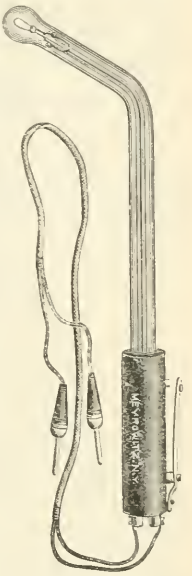
DIAGNOSTIC TRANS-ILLUMINATION OF THE SEPTUM NASI.

By J. H. MARTINDALE, M.D.,

MINNEAPOLIS, MINN.

A few months ago, having stumbled upon the use of the incandescent lamp as a means of septo-nasal transillumination, I would present the same to the readers of the Medical Record.

As all nasal specialists know, the presence of an enchondroma or exostosis of the septum is very frequently associated with deflection of the septum, the point of concavity on the one side being often exactly opposite the point of growth upon the other; hence the possibility, when removing by saw or trephine, of perforating through the septum into the opposite nasal space. To avoid this, septometers, devised upon the principle of the ordinary calliper, have been used, the operator relying usually, however, upon his own good judgment. By the use of the little nasal lamp, an illustration of which is herewith presented, a very graphic picture of the gross thickness at the point upon which he would operate is afforded. Briefly speaking, the lamp is contained in a piece of heavy barometer tube, properly electrically connected, and so constructed as to be easily kept aseptic in the true surgical sense of the term. The one Messrs. Meyrowitz have constructed for me has a brilliancy of two-candle power, and is easily illuminated by a four-volt storage or primary cell-battery. Its method of use is as follows: Having thoroughly cleaned and anæsthetized the nares, the operating-room is darkened (or an opaque cloth thrown over the head of both operator and patient). The trans-illuminating lamp is now introduced as far as possible into the nasal fossa opposite the side of operation, and the electricity switched through the lamp. Upon examining the side of operation with the nasal speculum, the light will be easily projected through the normal tissues, and intercepted at the points of abnormal thickening, the result being that the mind grasps through the eye a vivid and sufficiently lasting impression of the points where dense opacity indicates that removal may be boldly and freely attempted without fear of perforation.



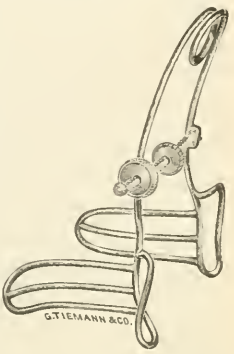
Only use of this little instrument will fully convince the operator of its value.

LABIAL RETRACTOR.

By D. A. CURRIE, M.D.,

ENGLEWOOD, N. J.

During operations for mending the perineum, I have been so much inconvenienced and delayed by assistants allowing the speculum and retractors to constantly slip and become misplaced, that the above instrument suggested itself to my mind. It is self-retaining and of three different sizes and two different lengths. My experience with it has been that the work of preparation goes on more rapidly with its use than with that of two unskilled assistants.



Some one may have discovered the device prior to this, but neither Messrs. Tiemann & Co. nor myself have seen or heard of it.

Those wishing to try one will find the narrow, short blade the more generally useful for perineal operations.

NEW CILIA FORCEPS.

By FRANK ALLPORT, M.D.,

MINNEAPOLIS, MINN.,

PROFESSOR OF CLINICAL OPHTHALMOLOGY AND OTOLOGY IN THE UNIVERSITY OF MINNESOTA, ETC.

I WISH to call attention to a pair of cilia forceps, devised in 1880 by myself. I have endeavored to use other forceps, but have always returned to the instrument referred to, of which a cut is here given, much

reduced in size. They are strongly made, easy to handle, and the points are of such size and shape as to enable the operative to grasp firmly and tenaciously the smallest hair. They are manufactured by E. B. Meyrowitz.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

HOSPITAL SUNDAY—COLLEGE OF SURGEONS—NEW BY-LAW—ELECTION—MEDICAL REPORT TO COUNTY COUNCIL—PROGRESS OF BIOLOGY—PROFESSOR HUXLEY—THE LATE SIR G. PORTER—DR. CASE—SURGEON-MAJOR CARTER.

LONDON, June 21, 1895.

THIS week opened with Hospital Sunday, when collections were made at almost all the Metropolitan churches of all denominations. The returns are necessarily incomplete, but nearly £15,000 is already reported as the result, and this amount is about £1,000 above that received in the same time last year. Perhaps, therefore, the total contributions may be an advance over last year. Certainly, the hospitals need more than ever, and it is high time London roused itself to its duties in this matter. It is to be hoped, too, that the distribution of the fund will this year excite fewer heart-burnings and that the dead set of a few prejudiced men against specialism will not repeat the injustice that has more than once been done.

The College of Surgeons has obtained the necessary sanction for a by-law which will enable the Council to remove from its roll the name of any Fellow or member adjudged, after due inquiry, to have been guilty of disgraceful conduct in any professional respect. This will give the college the power of maintaining a control over erring individuals which it has never shown much desire to exercise.

There are five vacant seats on the Council to be filled up on July 5th. All the candidates are prominent surgeons, and the election excites a good deal of interest among the Fellows who elect. The members have no part nor lot in this as in other college matters.

Mr. Shirley Murphy's second annual report to the London County Council has appeared, and will interest all sanitarians. It differs considerably from the Registrar-General's Report, applying, as it does, only to the County of London, and giving an account of the sanitary work of the Council, as well as the vital statistics of the population. Among other statistics is a London life table compared with tables prepared by other health offices, and "it is interesting to note that at each age and for each sex the expectation of life in London exceeds that in Manchester and Glasgow, but is less than that of Brighton." Some very important points are raised in reference to diphtheria and scarlet fever, especially one as to the influence of schools, for a considerable fall in the number of cases coincides with the summer holiday.

Professor Ray Lankester, in lecturing at the Royal Institution, lately, on the "Progress of Biological Science," gave some account of the rapid development of bacteriology. He did not accept the influenza bacillus; but among diseases undoubtedly caused by bacteria he named anthrax, phthisis, leprosy, and glanders. He held that Koch has proved that cholera is due to a spirillum which breaks up into comma-shaped segments, the comma-bacillus. Typhoid, tetanus, diphtheria, and erysipelas were also microbial diseases. He made some observations as to water which have been misinterpreted by the public press. Typhoid and cholera microbes he found would live in very pure water. Typhoid microbes would survive and multiply in distilled water for three or four weeks, but in ordinary river-water it soon perished from the poison of ordinary putrefactive bacteria. So far, river-water might be less dangerous than very pure lake-water in certain circumstances. Thames water of course teems with organisms which destroy typhoid bacilli, but that is not a reason for drinking Thames water, though it may give hope that typhoid pollution need not be permanent. The mention of filtration was then considered. The growth of those bacteria which are arrested in the sand of the great filter beds forms a sort of jelly which not only prevents the passage of solid particles through the sand but kills the germs of typhoid. The filter beds of well-conducted water-works are therefore a great protection. Not so, however, with the domestic filter, which Professor Lankester pronounced more dangerous than otherwise, for he had found bacteria-free water after passing through such a filter had taken up 200,000 to the cubic centimetre. Any domestic filter to be of use would have, he said, to be sterilized every twenty-four hours. This would certainly be a pleasant occupation for the ordinary domestic servant, and I fancy paterfamilias will neither undertake to look after his filter himself nor yet trust his cook to carry out the necessary proceeding. The lesson, therefore, would seem to be to get rid of our filters until something more efficient than the packings hitherto in use shall be discovered.

The action of different bacteria in presence of each other was also illustrated by the lecturer.

Professor Huxley's illness has for some weeks given great anxiety to his friends and admirers. Influenza was followed by serious pulmonary mischief, and now, just when he was said to have rallied from this and it was hoped he would enter on convalescence, I hear that nephritis has appeared and his condition is very grave.

The death of Sir George Porter on Sunday last removes a conspicuous name from the roll of Dublin surgeons. He was the son of W. H. Porter, the eminent professor of surgery, whose writings on "Aneurism" and other subjects will be well known to your readers, and well has he sustained his father's reputation. He has been loaded with all the dignities open to the highest professional rank—has been president of his college, professor in the University of Dublin, senior surgeon to his hospital, and admittedly at the head of the Dublin school. Besides the baronetcy he was Deputy-Lieutenant of Wexford and served as high sheriff in 1887. Through all his honorable career he has had the esteem and confidence of his brethren.

Dr. W. P. Case, medical officer of Croydon Union and member of the Town Council, died on the 11th instant.

Surgeon-Major Henry John Carter, F.R.S., whose work on the "Geology of India" and other writings were of the highest standard, died last month at his birthplace, Budleigh Salterton, to which he retired in 1862 after a brilliant Indian career. At that time the Royal Asiatic Society voted him £100 and later he received the Royal Medal of the Royal Society. Other honors from various societies had previously been showered upon him. He was in his eighty-second year.

THE CATHOLIC CHURCH AND ABORTION.

To the Editor of the Medical Record.

Sir: In the cause of legitimate medical science I wish to present the following in answer to the article in Medical Record of February 2, 1895, entitled "The Catholic Church and Obstetrical Science." I will first briefly set forth the teachings of the church's recognized moralists, supplemented by authoritative decrees.

Abortion is the ejection from the maternal womb of the immature fœtus, and may result from either natural or artificial causes. Now, the earliest period when the immature fœtus can live outside the mother's womb varies from the twenty-eighth to the thirtieth week of gestation. A fœtus delivered at this age would, it is true, be weaker than the mature one, but if the mother's health demands it, the church hinders not this acceleration of labor, since nothing is done directly against the child's life.

The second principle on which theologians are agreed is that it is *licet* to employ remedies which have their direct effect to remove the disease of the mother, although it is foreseen that the ejection of the immature fœtus will follow. For instance, if blood-letting were required to relieve the mother from some malady, it could be performed, even though it were foreseen to be fatal to the fœtus. The reasons here are evident, for the death is not a *per se* effect, but an accidental consequence, which the mother is not bound to obviate. A still more difficult phase presents itself when it is seen that the fœtus will cause the death of the mother before it arrives at a period when a hope might be entertained of its life if delivered. Here opinions differ, and some condemn what others allow. As I am unwilling to restrict the liberty of the medical profession within any narrower limits than those absolutely required, I will follow the opinions of the most liberal exponents of the faculties allowed by the church. I find that the Jesuit Lehmkuhl is most liberal on this point. In the first place he denies that any mother is rigorously bound to undergo the Cæsarean operation, especially where conscientious physicians judge that it is far more dangerous than accelerated labor. If, however, the danger to life is no greater from the Cæsarean operation than from the abortion, the mother would then lose her right to select the latter instead of the former, as there would be no motive in so doing. But if, all things considered, a moral certainty points to abortion as the only means of saving the mother's life, Lehmkuhl allowed the induction of artificial labor, at that time when the fœtus has so far progressed that it actually menaces the mother's life, even though it has not evolved to that extent that it could live in the medium outside the mother's womb. Von Olfers also allows such practice, although Dr. Capellman condemns it without reserve. I have never seen any theologian that allowed it save only Lehmkuhl, but, as his book has the imprimatur of Rome, no one will do wrong in following such opinion in practice. Of course, Lehmkuhl forbids in such case any direct act tending to take the life of the fœtus, such as diminution of the fœtus, perforation of the cranium, etc. That which he would permit would be, for instance, the effusion of the liquor amnii, which would render the expulsion of the fœtus a necessary consequence, though it would not *per se* invade the life of the fœtus. This again cannot be done to prevent an anticipated danger to the mother, but can only be done in the actual existence of the danger. I believe this then to be a probable opinion, and a physician can act upon it; but it certainly is the most liberal faculty given to the medical profession by theologians.

In relation to the operation known as craniotomia or cephalotripsia, all the theologians of the church are as a unit that it is never allowed, under any conditions, while the fœtus is alive. The ethical reasons for this prohibition are founded in the canon of the Almighty against murder of the innocent. From the moment of the conception of that fœtus it is a human person, having rights the same as every other human individual. To take its life by any direct invasion is murder, and no good results can ever justify a thing intrinsically wrong. That it is in a helpless condition and can neither plead for nor defend its right to live aggravates the crime. No plea that the infant is an invader of the mother's right to life can avail here, as the mother herself in her malformation is the aggressor, preventing the infant's right to be born. Let us illustrate this by an example. Two men are on a desolate island with no food. Will any man defend that one has a right to kill the other to save his own life? Or, perhaps, we may find a more apposite example. Two men are enclosed in a room with a limited amount of oxygen. If both go on respiring, they will both die before help comes; if one only were there the supply would last till liberation. One of them is asleep, and the other slays him while he sleeps. No man who advocates craniotomia can reprobate the killing of the sleeper. All doubt is removed by the authoritative declarations of the Congregation of the Holy Office, and also by the Council of Baltimore, which was approved by Rome. The Congregation, after having examined the book in defence of craniotomia written by Pennacchi, professor of history in the Propaganda, decided that the doctrine could not be taught. The Baltimore Council says: "Neither is it allowable to any mother, whatever thing may befall, even to the saving of her life, to permit the death of the child in her womb." It is true that Catholic writers have defended craniotomia, but they have always been condemned, and their authority is thus neutralized by the church's condemnation.

What Lehmkuhl says about leaving the physician in good faith, he distinctly affirms does not render the operation *licet*, but he counsels it to be at times expedient when it is foreseen that a prohibitory injunction from the priest would do no good. If I foresee that an eminent physician is set upon performing the diminution of the fœtus, it is left to my prudence to try to stop him or not, and Lehmkuhl counsels them to leave him in good faith when a prohibition is foreseen to be futile. But this is far from approving such act in itself. Again I am surprised to see the writer of the aforesaid article confuse the issue set forth by the cardinals at Rome and an issue dealt with antecedently by the Grand Pœnitentiary of Rome. The decision of the congregation of cardinals is the decision of the Holy Office before mentioned, and was that the defence of craniotomia could not be taught. This decree is the latest on the subject from Rome, and was given in 1884. The other decree was given by a special officer at Rome, delegated to confer upon cases *in moral* and answer them, and was in 1872. The said Grand Pœnitentiary was asked whether craniotomia could ever be allowed by a priest, and he made answer: "Consult the approved authors, and act prudently." Now, in the first place, here the authors are not, as the writer quoted by the Medical Record states, authors of medical works, but of moral treatises, as the word author in ecclesiastical language standing alone always implies a theologian. Again, the response simply declined to define the issue then, which was finally settled in 1884, and allowed the priest only the safe opinions which were then found in good theologians. The clause, "act prudently," simply warned him that, at times, it were better to allow a physician to go on in good faith in the execution of an illicit act than to interpose a futile prohibition. If then the end cannot justify the means, which is a basic principle of morality, I see not how physicians can approve a practice which is a stigma on their high profession. Craniotomia is especially reprehensible to-day since by the employment of the aseptic mode of operation eighty per cent. of mothers live through the Cæsarean operation, a percentage not equalled by those saved by abortion.

The number of infants safely delivered by the section is about in the same proportion, hence one may easily see the motives in favor of the Cæsarean sectiom, and yet in America craniotomia is the order of the day, while the section is rarely operated, unless when the physician is forced to it by the principle of the mother. Physicians, who are the defenders of life, should cultivate ambition for their high profession which the common feelings of humanity could approve.

A. E. Breen, D.D.,
Professor of Holy Scripture in St. Bernard's Seminary, Rochester, N. Y.

ON THE PHYSIOLOGICAL ACTION OF PERIODIC INDUCED CURRENTS.

To the Editor of the Medical Record.

Sir: If Dr. Rockwell did not intend to criticise my claims, it is by no means clear why he wrote his first letter; but we will accept his assertion to this effect.

In my presentation of what I deemed to be self-evident facts I may have failed, in my previous communication, to convey precisely what I desired. This seems to have led Dr. Rockwell into some misapprehension, but when more fully explained I think he will agree with me that further discussion is unnecessary.

I maintain that the manufacturer referred to did ask my consent to wind upon one secondary helix all of the various sizes and lengths of wire originally suggested only by me, and that it was perfectly proper for him to have done so, since I had a right to say what should be put upon the market under the name of "The Goelet Induction Apparatus." It was distinctly understood that I should test the apparatus after it was so constructed, and that I would give it my indorsement only if it was found to be as satisfactory as when the different sizes of wire are wound upon different helices. The apparatus was sent to me for approval and after testing it carefully I gave it my indorsement. For more than a year previous to this time two other manufacturers had been making the apparatus with four interchangeable coils. In a letter I received from one of these manufacturers shortly after my paper appeared suggesting this combination of coils and giving the different sizes and lengths of wire required, the statement was made that it was the only practical suggestion which had been published up to that time, regarding the construction of faradic apparatus and the needs of the profession.

Dr. Rockwell is mistaken in supposing that the manufacturer referred to above constructed for him previously a continuous coil of nearly two thousand yards, made up of the same sizes and lengths of wire mentioned by me. In fact no such apparatus with these sizes and lengths of wire or anything like it had ever been manufactured or described at the time I made the suggestion at the first meeting of the American Electro-Therapeutic Association in 1891. If Dr. Rockwell thinks he described such coils in his article in the Medical Record on February 14, 1891, he is mistaken, and anyone interested can see his mistake by carefully perusing that article. The coils there described were continuous with the primary, and no sizes nor lengths of the wire were mentioned.

It is neither my disposition nor desire to point out any marked inconsistency in a colleague's communication. Dr. Rockwell's may have been written in haste. But I feel obliged to call his attention to the fact that he begins by disputing my rights and ends by suggesting that he and I have had quite different things in mind.

A. H. Goelet, M.D.

June 18, 1895.

A Chinese Maxim says that when doctors go afoot and men of letters drive in their own carriages, the empire is well governed.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 6, 1895.

	Cases.	Deaths
Tuberculosis	129	74
Typhoid fever	9	1
Scarlet fever	33	6
Cerebro-spinal meningitis	0	7
Measles	198	24
Diphtheria	185	42

Fencing from a Hygienic Stand-point.—According to Lecomte fencing is a hygienic exercise of the first rank and even a curative means for certain deformities. This exercise should be practised in a well-ventilated room, under the direction of a *maître d'armes*, who insists on the correct execution of the movements and unrestrained postures. It is indispensable to use the left hand also, in order to develop the two sides of the body equally. Under the influence of this exercise the muscles develop, the joints and spinal column are suppled, the respiratory, circulatory, and digestive functions are rendered active; nutrition and the nutritive changes are stimulated at the same time as the cutaneous functions. Fencing has given excellent results in hysteria, chorea, migraine, hypochondria, insomnia, obesity, gout, rheumatism, constipation, and chlorosis. It assures recovery from scoliosis and from stiff joints following immobilization, and corrects certain cachectic deviations of the lower limbs.—*Journal of the American Medical Association.*

The Use and Abuse of Antipyretics.—At a recent meeting of the West London Medico-chirurgical Society, a report of which appears in the *Lancet* for May 11th, Dr. William Hunter read a paper in which he pointed out that the extent to which antipyretic agents were used and their manner of employment were greatly influenced by our views of fever. After considering the analgetic properties of the more recently introduced antipyretics derived from coal-tar products, such as antipyrine, phenacetine, and acetanilide, he said that the control of the nervous system was one of the principal points in the treatment of fever. The proper object of using such drugs was not to abolish fever by a summary process, but rather to bring the febrile process within reasonable limits. The administration of these remedies, he said, should always be cautious, more particularly in the case of acetanilide, the usual dose of which, as given in books (from three to ten grains), was much too large; it should be from one to three grains. Dr. Banning remarked that no antipyretic equalled the use of cold sponging and wet packs, either in efficiency or in safety. Dr. Eccles believed that the direct action of antipyrine could be attributed to its reducing qualities, removing oxygen from the protoplasm of the nerve-cells, and thus diminishing activity and producing analgesia. Dr. Atkinson said that he had not found any benefit follow the use of antipyretics, and thought that, as the temperature always fell before death, high temperature by itself would not kill a patient. Mr. McAdam Eccles referred to surgical cases where high temperature was due to nerve-influence, especially in cases of head injury followed by high fever without sepsis, and to the so-called catheter fever. He said that after injuries of the head the temperature was often different on the two sides.—*New York Medical Journal.*

Epidemics of Typhoid Fever have lately been traced in Calcutta and Bombay to the use of watercress which grew in soil polluted by sewerage.

COMPARATIVELY PAINLESS MASTOID DISEASE.[1]

BY ALBERT H. BUCK, M.D.,

NEW YORK CITY.

CLINICAL PROFESSOR OF DISEASES OF THE EAR IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; CONSULTING AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY, AND THE PRESBYTERIAN HOSPITAL.

Of all the symptoms which characterize both the acute and the chronic forms of disease of the mastoid process, that of pain is, I believe, the most constant. Hyperæmia and œdema of the skin behind the ear, and tenderness on pressure over this region, are often lacking. Elevation of the body temperature is as often absent as it is present, and that, too, even in the cases which are characterized by the presence of pus in the mastoid cells. The existence of a perforation in the membrana tympani, and the escape of a more or less purulent discharge from the middle ear through this perforation, may also exceptionally be absent from the list of symptoms belonging to a case of mastoid disease. And, finally, we may even fail to find that prolapsed condition of the upper cutaneous wall of the inner half of the external auditory canal which furnishes so trustworthy an indication of the inflammation going on in the adjacent bone. But in the vast majority of cases pain has not only been an unfailing symptom throughout a period of at least several days, but has usually constituted the most striking feature of the disease. In this statement I believe that I correctly reflect the experience of all those who have had much to do with the various forms of mastoid disease. During the early months of the present year, however, I have encountered a few cases in which the symptom of pain has occupied such a markedly subordinate position that I have thought it might serve a useful purpose if I should report them.

There are four of these cases, all of them of an acute character and all of them characterized by pain at the onset—that is, at the time when, presumably, the inflammation was still confined more or less strictly to the tympanic cavity. After this initial period, which lasted from a few hours to two or three days, there was either no pain at all (as in Cases II. and III.), or the pain was of such a migratory character and so little pronounced (Case I.), as scarcely to attract the attending physician's attention to the ear as its starting-point; or, finally (Case IV.), this symptom only developed when some special exciting cause—like violent physical exercise—was brought into play as a means of calling it forth.

I have endeavored to formulate some sort of an hypothesis which might explain with some degree of plausibility this coexistence of serious inflammatory disease in the substance of the greater part of the mastoid process with little or no pain in the affected region, but I have not succeeded in finding an entirely satisfactory explanation. There are doubtless several varieties of micro-organisms which are competent to cause, and actually do cause, such mastoid disturbances as were found to exist in these four cases; and it is a permissible inference that the toxins produced by these different varieties of organisms differ in their composition and in the effects which they produce upon the tissues that come in contact with these juices. I would therefore venture to suggest the possibility that among the various living organisms which, in suitably constructed mastoid processes, produce serious inflammation and ultimately destruction of the tissues involved, there may be one or more species which create toxins possessing a decidedly anæsthetizing power over sentient nerve fibrils. As a proof of the reasonableness of such a belief, I need only to point to the painlessness of tubercular inflammations of the middle ear.

But the etiological aspects of these cases are, it seems to me, of far less importance than their practical bearings, which may be briefly summed up as follows: First, serious disease of the mastoid process may coexist with an insignificant amount of pain in the affected region; and, second, of all the physical evidences of disease in this part of the temporal bone the one that is most rarely lacking is a prolapsed condition of the skin lining the upper and posterior wall of the external auditory canal in close proximity to the membrana tympani. (At a more advanced stage of the disease, or under more favorable anatomical relations, this prolapse may extend throughout the entire length of the canal.)

CASE I.—Female, fifteen years of age, and apparently in robust health. About January 4, 1895, she, along with several members of the family, was taken ill with what seemed to be the grippe. Very soon afterward she complained of pain in the ear and at various points on the right side of her head. These pains were supposed to be of a purely neuralgic character, as they finally centred themselves in the region of the right cheek. Her temperature at this time was found to be 104° F. In the course of a day or two she seemed to have recovered her usual health and was permitted to return to school.

On January 10th the pains in the ear and on the right side of the head returned, but were not specially severe and soon passed away entirely. She felt considerable general malaise, however, and her temperature was found to be decidedly above the normal (104° to 105° F.). As the pain was referred sometimes to one side of the head and sometimes to the other, and as other members of the family were ill at the same time with what seemed to be the grippe, it was believed that the elevation of the temperature was attributable wholly to the action of the grippe poison, and that the pain was of a simple neuralgic character and not dependent upon any local inflammatory action. Nevertheless, the attending physician examined the ears and found a little congestion of the right membrana tympani; but it did not seem to him that it was sufficient to explain either the elevation of temperature or the pains occasionally experienced by the patient. *At no time after January 10th did she experience any pain in the right ear.*

On the morning of the 13th she had a decided chill and the temperature rose to 105° F. It was then thought that the ear trouble might be more serious than was at first supposed, and I was accordingly asked to see the patient. On examination I found the posterior superior quadrant of the right membrana tympani and the immediately adjacent soft parts red,

[1] Paper read before the American Otological Society at its annual meeting July 16, 1895.

swollen, and tensely convex. On expressing my surprise that she was not in suffering on account of this localized inflammation, the patient reiterated the statement that she had no pain in the ear, but simply felt the beating of her pulse in that locality. A free incision was made (without the aid of an anæsthetic) and a drop of pinkish pus (quite thick) was evacuated. For several hours afterward the ear was frequently douched with hot water, and hot flaxseed meal poultices were kept applied the greater part of the time. Calomel was also administered every hour in one-tenth-grain doses.

On the 14th I found that she had vomited twice during the night and that her temperature had not gone below 104.5° F. No perceptible discharge from the ear had yet shown itself.

On the 15th I found that she had again vomited during the night, that her temperature remained high, that she had experienced no pain in the ear, and that despite the douching and frequent poulticing no discharge whatever had made its appearance. An examination revealed the fact that my incision had completely healed, and that the posterior and upper part of the drum membrane still formed with the adjacent soft parts a protruding red mass of skin of a somewhat parched aspect. Slight tenderness on pressure over the central part of the mastoid process was also found to have developed since the previous visit. I accordingly advised that the mastoid process be opened without further delay, and this operation was performed on the same day. The conditions found were the following: The antrum filled with pus and granulation tissue; the bone in the immediate vicinity of this cavity perceptibly softened; everywhere else throughout the mastoid process a high degree of hyperæmia and abundant granulation tissue in the pneumatic cells.

On the morning of January 16th, the day after the operation, her temperature was found to be normal and it remained so from that time forward. Her pulse-rate also fell to 90, and in the course of another day or two it fell to 72, and remained at about that rate afterward. Before the operation the pulse-rate had varied from 104 to 108.

The external wound closed on January 28th.

Case II.—Child, six years old, in good general health. I was called to see the case, for the first time, on May 17, 1895. The parents stated that six days previously their daughter had complained of pain in the left ear, and that soon afterward a discharge from this ear was noticed, but that it had lasted only about one day; and that from that time to the day on which I saw her, there had been no further complaint of pain in the ear. The temperature, however, had varied from 102° to 105.2° F. On examination, I found the left membrana tympani red and markedly bulging. There was no redness or tenderness of the skin behind the auricle of the affected ear. An anæsthetic was administered, and I made a long crescent-shaped incision in the left drum membrane, giving vent to a little pinkish pus. Frequent douching with hot boric-acid solution was prescribed. A rather scanty discharge continued during the next twenty-four hours and then ceased entirely.

May 23d.—There has been no further discharge from the left ear since the 18th, but on the afternoon of the 21st I found a drop or two of yellowish pus at the inner end of the external auditory canal. From day to day, however, I have noted a slowly increasing prolapse, downward and forward, of the skin lining the upper and posterior portion of the osseous external auditory canal; this condition being first noticeable in the vicinity of the membrana tympani. The child has made no complaint, at any time, of pain in the ear, and she has acted as if she were entirely free from any such distress. Furthermore, the membrana tympani has steadily grown paler and more natural in appearance, and every attempt to elicit any sign of distress, when I pressed firmly upon different parts of the left mastoid process, has failed. Day after day, however, and despite the fact that she has taken daily, for three or four days in succession, from twelve to fifteen grains of quinine, the body temperature has risen every afternoon to 104° and even 105° F.

May 24th.—Still no complaint of pain, and no evidence of any distress. But the temperature continues to rise to 104° or 105° F., and early this morning the child vomited. There is also now a little tenderness over the central part of the mastoid process, and the prolapsed condition of the cutaneous wall of the canal continues, although it is perhaps less marked than it has been. Operation advised and performed during the afternoon of the same day. When the outer surface of the mastoid bone was laid bare, the peculiar shaven-beard appearance commonly observed in the stage just preceding that of actual necrosis was recognized over a central area about as large as a three-cent silver bit. This corresponded to the only spot where tenderness on pressure had been elicited at the last moment. A high degree of venous hyperæmia (the blood was unusually dark) and the filling up of many of the pneumatic cells and the antrum with granulation tissue were the only lesions noted. Pus was not found at any point; but if any of the cells had contained pus the copiousness of the bleeding would not have permitted us to recognize its presence.

The subsequent progress of the wound was every way satisfactory. Healing took place without the formation of more than a few drops of pus. The skin behind the wound remained perfectly normal in appearance. The child made no complaint of pain in the ear, and ate and slept quite well. But every afternoon her temperature rose to a high level—rarely under 104°, and on one occasion as high as 107° F. The administration of quinine was again resorted to, and it was found to exert a limited influence upon the temperature. The doses were increased until the child finally took twenty-seven grains in the course of twenty-four hours. This brought on vomiting, and it was then decided (June 10th) to remove the child from her residence, in the upper part of the city, to the country. Since that time I have heard no further news of the child's condition.

Case III.—Child, about six years old. General health always good. Mild attack of scarlet fever early in April, while absent from home. Child complained of pain in the right ear for two or three days, a discharge then made its appearance, and from that time onward she made no further complaint of pain. She ate and slept well, and played with her toys as if she felt perfectly free from pain. The discharge was at no time abundant, but it gradually diminished in quantity until, at the time when the preceding statement of the case was made to me by the child's father (May 7, 1895), it had very nearly ceased. As the family expected to sail for Europe on May 22d, and as the child could not conveniently be brought from the country before the 20th, the father wished to know whether he might safely postpone bringing her to see me until that date. I replied that I believed, from his account of the case, that he might safely allow the child to remain in the country until the time mentioned.

On May 20th the child was brought to New York, and I examined the affected ear. The external auditory canal was of normal size and appearance and contained a little stringy mucus which escaped through a very small perforation in the centre of the membrana tympani, which was entirely free from hyperæmia, but showed a little fulness in the vicinity of Shrapnell's membrane, chiefly posteriorly. Usually I attach great importance to this condition, but as the child had experienced no pain in the ear for several weeks past, as there was neither redness nor tenderness of the mastoid integuments, and as the discharge appeared to be of a

purely mucoid character and very scanty, I made up my mind that no serious significance should, in this particular case, be attached to the slight prolapse of the skin at that part of the external auditory canal which corresponds to the floor of the mastoid antrum. I therefore dismissed the case as one which needed no further active treatment until the family should reach London and could obtain the services of some physician competent to thoroughly remove a fairly large mass of hypertrophied adenoid tissue which I had discovered in the vault of the pharynx.

The following morning (May 21st) the child complained of pain in the right ear, and soon afterward the nurse discovered that the skin behind the ear was red and swollen. Her temperature was taken and was found to have reached 103° F.

On the following day—that on which she was to have sailed for Europe—I operated and found that pus was escaping outward through a very fine opening in the cortical portion of the mastoid process. The bone substance in the immediate vicinity of this small opening appeared to be dead. Pus, abundant granulation tissue, and softened bone structure were found throughout the greater part of the mastoid process. The activity of the bleeding and the abundance of granulation tissue found at this depth made it impossible for us to determine whether the antrum contained any pus or not. A considerable area of softened bone was removed from the region situated directly above and behind this cavity.

On the eighth day following the operation the outside wound had entirely healed. A slight mucoid discharge, however, still continued from the external auditory canal; but this ceased entirely on the fourth or fifth day after the removal (by my associate, Dr. Robert Lewis, on June 3d) of quite a large adenoid growth from the vault of the pharynx. A decided improvement in the hearing also became noticeable at the same time.

Case IV.—Male, sixteen years old, in good general health. About April 15, 1895, he experienced a sharp pain in the right ear. Dry heat was applied and he obtained relief in the course of a few hours. During the following four weeks he occasionally, for brief periods of an hour or two, experienced a little pain behind the same ear. There was no discharge at any time from the external auditory canal, and his general health seemed to be comparatively little affected by the condition of the ear. He made the impression upon his parents of being more nervous and irritable than usual, and his general appearance and manner led them to believe that he was perhaps overworked. Nevertheless, all through this period, he indulged freely in athletic sports.

On May 14th he had a second brief attack of severe pain which he referred to the region behind the right ear. Movements of the head aggravated the pain.

On May 15th I saw the patient for the first time. The hearing power of the right ear was then noticeably diminished. There was some drooping of the upper and posterior cutaneous wall of the external auditory canal throughout its entire length. The soft part behind Shrapnell's membrane was also somewhat more prominent than natural, and the membrana tympani itself presented a dull and soaked appearance, but without any bulging of the membrane outward. There was no redness or swelling of the mastoid integuments, but there was some tenderness when I pressed firmly upon these parts.

Systematic poulticing and rest in bed were advised. On May 22d I saw the patient again. The parents reported that under the treatment suggested the pain and tenderness on pressure had rapidly disappeared, the temperature had returned to the normal height, and the boy had seemingly obtained complete relief from his ear trouble. On examination I found that the drooping of the upper wall of the inner half of the canal had greatly diminished, but had not entirely disappeared, nor had the slightly prolapsed portion of skin near Shrapnell's membrane, posteriorly, returned to its normal situation. Aside from these two points there was absolutely nothing to indicate that the mastoid process was not in a condition of perfect health. Here again I felt disposed to look upon these slight departures from the normal condition as simply indications that the mastoid process had not entirely recovered from its recent inflammation, but that the remaining osteitis was insignificant in degree and extent. I accordingly advised the patient to go about again as usual, but to avoid athletic sports until he felt sure, by actual experiment, that his ear was once more able to bear the unusual strain.

On May 23d, still feeling quite well, he indulged during the forenoon in a single game of tennis, and walked a short distance. Early in the afternoon the pain in the mastoid region had returned, his temperature rose to over 102° F., and the skin behind the ear once more became red, swollen, and tender. Prompt and continued poulticing, with rest in bed, soon relieved the pain, swelling, and tenderness behind the ear, and restored the body temperature to a little over 98° F.

On the 25th I found him free from all pain, with a normal temperature, with no redness or swelling of the mastoid integuments, and with only a little tenderness on firm pressure over the central and lower part of the mastoid process. The history of the case, however, showed so plainly that a focus of disease must still be lingering on within this portion of the temporal bone that I urged the advisability of an immediate operation. My advice was accepted and the operation was performed during the afternoon of the same day.

After the surface of the bone had been laid bare, and the mastoid hook guide had been put in position, I applied the chisel at the usual spot, just behind and a little above the knob of the hook—that is, just behind and a little above the curving posterior and upper margin of the entrance to the osseous external auditory canal—and removed a single chip of bone substance about one millimetre in thickness. Immediately underneath this thin piece of bone lay what seemed to me to be slightly bluish granulation tissue. Exploration with the probe, however, revealed the fact that it was the outer wall of the lateral sinus, which in this case occupied a position not only unusually far forward, but also much nearer the surface of the skull than I remember ever to have seen it before. On further removal of the bone in a downward direction it was found that the central and lower part of the mastoid process was converted into quite a large abscess cavity, into which the curving portion of the lateral sinus projected to the extent of two-thirds or more of its circumference. All this exposed surface of the vein was covered with small elevations of granulation tissue, but the vessel was thoroughly elastic, and it was evident that the blood was still flowing through it in a natural manner. By cautious chiselling and spooning with a Volkmann's spoon directly behind the vertical portion of the lateral sinus, I succeeded in reaching the antrum. No recognizable pus was found here, but abundant granulation tissue was removed both from this cavity and from the adjacent pneumatic spaces.

The further history of the case presents no features of special interest. The wound healed naturally and promptly and no drawbacks of any kind occurred during the patient's convalescence.[1]

[1] It seems to me that no case could illustrate more forcibly than this does the danger which attends the employment of the drill as a means of establishing a drainage channel between the mastoid antrum and the outer world. Having been in former years a strong advocate of the use of this instrument, I feel as if now it were peculiarly incumbent upon me to lose no good opportunity of warning against its employment.

A NEW METHOD OF TREATING ADHERENT RETROPOSED UTERI.

By WILLIAM R. PRYOR, M.D.,

PROFESSOR OF GYNECOLOGY, NEW YORK POLYCLINIC; VISITING SURGEON, CITY HOSPITAL (GYNECOLOGICAL DIVISION).

SURGICAL procedures, and mechanical as well, which seek to correct retropositions of the uterus, may be classed under two divisions: they correct the displacement either by maintaining the cervix high up or by drawing the corpus uteri forward. This classification applies to the adherent as well as movable forms of retrodisplacement, only in the former the adhesions must first be broken up. The organ may be released either by working from the vagina, as by Sims's and Schultze's methods, or by abdominal section. Those who have performed cœliotomy for adherent retroposition find, as a rule, lesions of the uterus and adnexa greater than were revealed by the most careful examination, and have generally abandoned the forcible blind separation of the adherent organ by the vagina. So then, to-day, most cases are subjected to abdominal section and hysterorrhaphy. The possibilities and limitations of this operation are now well defined.

Suffice it to say that the operation is an eminently successful one, and there are but two objections to it: it converts a pelvic organ into an abdominal one, with fixation of the corpus uteri, and necessitates section of the abdominal wall.

In the effort to find some substitute for this too severe procedure, I made a careful study of my operations upon the adnexa through the posterior cul-de-sac, and became convinced that the proper method of treating these cases of adherent retroposed uteri was to be applied through the vagina.

Preparation of the Patient.—For two days before the operation the patient's vagina should be kept packed with iodoform gauze, soaked in $\frac{1}{5000}$ $HgCl_2$, for the purpose of loosening the superficial epithelium and straightening the rugæ of the vagina. Three days before the operation a calomel purge is given, and the night before two or three compound rhubarb pills. No enemata are given, as on the eve of the operation the patient is nervous, and much of the enema is retained to be rejected during the operation over the field of work. The abdomen and genitals are covered by a wet lysol dressing, one-half to one per cent., for twelve hours. The patient is shaved on the operating-table. Where there is marked intestinal torpor, strychnia may be given in small doses, grain $\frac{1}{60}$, t.i.d., for three days before the operation.

Operation.—The patient having been shaved and the vagina scrubbed, she is placed in the lithotomy posture. The instruments used are Péan's retractors and traction forceps, and Luer's forceps, in addition to those used for curettage. Strong scissors, curved on the flat, are also needed. The uterus is thoroughly curetted. If there be hypertrophy of the cervix, Schroeder's amputation is also done. Péan's traction forceps grasp the cervix and pull it down. When this is done, the point at which to enter the cul-de-sac is not easy of selection; but when the cervix is pushed up, a crescentic fold will appear behind it, as an index of where the vagina is reflected from the cervix. Just in front of this fold the mucous membrane is incised with the scissors in the form of a crescent, the ends of the curved incision stopping short of the lateral median line. Still making firm traction with the forceps, the fingers of the left hand peel back the vagina, the operator keeping his finger-tips pressed firmly against the posterior wall of the cervix. The anatomical fact must be here borne in mind that in some women the cul-de-sac is behind the entire vagina, while in others the peritoneum is reflected to the bowel from the uterus at the level of the internal os. Having separated the vagina as far up as the internal os, if the fingers have not already entered the peritoneal cavity, they are withdrawn and the opening wiped dry. A pouching will be noticed above, and is formed by the peritoneum. We open the cavity with one snip of the scissors, applied not against this pouch, but where it is attached to the uterus. One finger is inserted for exploration, and to break up adhesions. Should there not be sufficient room for this, the two index-fingers are introduced and laterally separated. This will open the peritoneum as wide as the lateral incision in the mucosa. Plenty of room is now obtained for working with two fingers. When all adhesions are broken up, a large iodoformized pad, to which is attached a string, is introduced into the pelvis, and the patient thrown into Trendelenburg's position. She is still on the back with legs flexed on abdomen. While she is in Trendelenburg's position, the intestines are made to enter the abdominal cavity, and another large pad, similar to the first one, is introduced. The table is now lowered to the horizontal. The Péan retractor is inserted into the pelvis with its upper end against the gauze, and the uterus is pushed up behind the symphysis by using the Péan trowel. In this way we look directly into the pelvis. The adnexa can be inspected and drawn into the vagina. If they require attention, it may be given them, or one may be removed. In other words, a part of that work which we apply to the adnexa through the abdomen can be applied through the vagina, provided we employ the Trendelenburg position, so that we can see what we are doing, and not have the intestines prolapsing into the vagina. Satisfied that the uterus is free, I now pack the organ with iodoform gauze. A wad of iodoform gauze with string and large enough to fill the opening in the peritoneum is now prepared and held in readiness. The posterior retractor is drawn down, so that the edge of the vaginal incision may be seen and grasped with forceps. The two or more pads in the pelvis are now withdrawn and the wad of gauze inserted into the opening just within the cut edges. The uterus and gauze are anteverted *en masse* by Brandt's method, great care being exercised lest we displace the wad of gauze. If the gauze be not in the incision, the cul-de-sac will not be drained, and no lymph will form posterior to the cervix. If the gauze be pushed up too far behind the cervix, it will reach the tubal ends, and they will become implicated in the lymph effusion. A good deal of manual dexterity is required to replace the uterus and leave the gauze wad in just the proper position behind the cervix. Gauze is now packed in the vagina in such a way as to keep the cervix forced high in the pelvis. To accomplish this the space occupied by the bladder must be encroached upon, so as to have one pillar of gauze from the cervix to the symphysis. This necessitates filling the vagina pretty snugly.

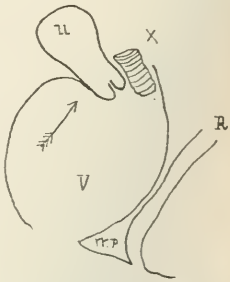

FIG. 1.—*U*, Uterus; *V*, vagina; *R*, rectum; *X*, wad of gauze. The cul-de-sac has been opened, the uterus replaced, and the wad of gauze placed in the incision. The vagina is distended with gauze which is not shown, but the direction of effort of the vaginal gauze is indicated by the arrow.

After-treatment.—Catheter every three hours for a day, after which the patient can take care of the bladder herself, usually. After the first day the catheter may be used every four to six hours, not more than four ounces of urine being allowed to accumulate at one time, unless the patient can empty the bladder when that quantity of urine accumulates. The bowels are to be moved in forty-eight hours, earlier if there has been pus in the uterus or pelvis. I use half an ounce of Rubinat water, with an equal quantity of the seltzer, until ten doses are taken or the bowels move. Enemata are not allowed. After the bowels have

moved, the patient may be permitted any light diet—toast, eggs, gruel, scraped beef, etc. The lower pieces of gauze in the vagina may be changed on the third day, as they are probably soiled by urine. If there has been much pus in the uterus, the uterine packing is withdrawn at this time. At any rate, it is to come out when the vaginal gauze is removed, and is not to be renewed. But care must be taken that the vaginal gauze be renewed as carefully and as snugly as the first was applied. The wad of gauze in the cul-de-sac is not disturbed for from seven to ten days. This is possible with one kind of gauze only.[1] In removing this wad of gauze Sims's position is preferable. The wad should be removed with great gentleness, and the cervix should be supported and not allowed to descend. A wad, smaller but similar to the first, is introduced into the opening and the vagina again filled with gauze. The patient is allowed out of bed on the tenth day. A week after the first dressing another is made, and five days later this is changed. Two, or at most three, dressings to the cul-de-sac are made, but the vagina is kept packed to support the uterus for a month. I usually select two days after the menstruation to operate, thus gaining abundance of time for after-treatment. After the cul-de-sac has closed, vaginal dressings of tampons soaked in ichthyol, ten per cent., and boroglyceride, ninety per cent., are used if the uterus be enlarged.

What the Operation Accomplishes.—The adhesions are severed and the possibly occluded tubes opened. The organ is lightened by curettage and cervix operatior, one or both. At the same time, the cervix is maintained in such an elevated position that the intra-abdominal pressure must be behind the corpus, thus throwing the organ well forward. By a slender band of false membrane, produced by hysterorrhaphy, we correct retroversion. My operation does the same thing by a dense mass of lymph about the utero-sacral ligaments. My operation leaves the corpus uteri free, does not invade the bladder space, and merely corrects errors in the relations between the pelvic viscera. All other operations substitute some other, perhaps less serious, malposition for the adherent retroversion or flexion.

I first applied this operation six months ago, and have used it seven times. All cases had one or both adnexa occluded. One had a small cystoma associated, measuring two inches in diameter, and but one (the last) presented pus in one tube. All operations were made in multipara except one. The exception was a case of gonorrhœic infection.

Two have been examined by Dr. Jacobs, of Brussels, and Dr. Etheridge, of Chicago. Two have been repeatedly seen and examined by the gentlemen of the Polyclinic. The last operation is too recent to report the result, except that she has nicely recovered.[2] In every case the uterus maintains an anteverted position. The operation is offered as a substitute for all other procedures applied to these cases. It is not a blind piece of work, but every step is under the eyes' guidance. It but retraces the steps along which the deformity occurred—descent, retroposition, infection—and corrects each. Plastic work upon perineum and vagina is not to be overlooked, but must be applied as in all other conditions demanding it.

Artificial Fever for Insanity.—An alienist in Vienna has been treating insanity by inducing fever through the injection of tuberculin. With each rise of temperature there is an improvement in the mental condition, and this improvement gradually, through constant repetition, becomes permanent.

[1] New York Medical Journal, May 18, 1895.

[2] This lady has been seen and examined by her physician since the operation. It is now five weeks since the operation, and she is up, without vaginal support, and the uterus in perfect position.

THE TREATMENT OF FIBRO-MYOMATOUS UTERI REQUIRING HYSTERECTOMY BY A COMBINED VAGINO-ABDOMINAL METHOD OF ENUCLEATION WITH INDIVIDUAL LIGATION OF BLEEDING VESSELS ONLY.

By J. COPLIN STINSON, M.D., C.M.,

HAMILTON, ONTARIO.

LATE HOUSE SURGEON, NEW YORK POST-GRADUATE HOSPITAL.

Technique of the Operation.—The patient is prepared as for any vagino-abdominal operation. After anæsthesia is complete, the patient is placed in the lithotomy position, and the perineum is retracted by Edebohl's retractor; lateral retractors are frequently also of great assistance. The first step consists in an exploratory incision into Douglas's sac to establish or confirm the diagnosis; next is circumcision of the cervix, made as near as practicable to the lower end of the cervix; hemorrhage from the vaginal arteries is thus reduced to the minimum; posteriorly the incision is continuous with that into Douglas's sac. The incision is carried through mucous into submucous tissue; now the cervix is seized with vulsella and drawn down well into the vagina and then separated from its surroundings by blunt dissection, aided at times by snips with the scissors. The forceps drag down the cervix, drawing the tissues adjacent to this organ taut, while the scissors divide them as close as possible to it. Now dissect off the bladder by keeping close to the anterior surface of the uterus—if it is possible to go high enough, open the anterior peritoneal pouch, or it may be opened from above later. By keeping close to the uterus with blunt dissection aided at times by snips from the scissors, you separate the broad ligaments on each side as high as you can. In carrying on the above dissection, if any vessel should spurt seize it at once with the forceps and ligate with a transfixion catgut ligature. The object in freeing the cervix and lower portion of the uterus from below is to simplify the further steps of the operation from above.

Next the abdominal incision is made to expose the fundus, tubes, ovaries, and fibro-myomatous masses. By blunt dissection, aided at times by snips with the scissors, you ablate the tubes and ovaries by carrying your dissection as close as possible to these structures. Bleeding vessels are ligated with fine catgut. Next continue the dissection close to the uterus, till the broad ligaments are separated on both sides down to the line of separation from below. Now, if the bladder has not been separated from below, you may partly distend this organ with a weak boracic solution; then, about one-half an inch above its attachment to the uterus, an incision is made and the remainder of the bladder separated.

Two principles are involved in the satisfactory performance of the combined vagino-abdominal enucleation of a fibro-myomatous uterus. The first is to dissect as close as possible to the uterus, tubes, and ovaries. Bleeding is thus reduced to the minimum. By this means you divide only arterioles or capillaries, the oozing from which stops almost at once. The second is to keep your immediate dissection well in view, and if any artery be divided to catch it at once with forceps and ligate with a transfixion catgut ligature. Enucleation with simple ligation of the bleeding vessel was, as a routine practice, first done by Pratt, of Chicago, to whom great credit is due, and the method justly bears his name.

After separation of the bladder from the anterior surface of the uterus with a few snips of the scissors, uterus, the fibro-myomata, tubes, and ovaries are lifted out of the pelvis. Now the peritoneum of the pelvic floor is closed with a running catgut suture, but if there are indications for drainage, then the floor is partially closed and the deep pelvis is lightly packed with gauze, the ends of which are brought down into the vagina.

Next the abdominal wall is closed in separate layers with chromatized catgut or tendon suture, and the dressing is applied. Strips of gauze are placed in the raw space between the vagina and closed or partly closed peritoneum, and finally more of the same gauze is placed in the vagina. A gauze pad is placed over the vulva. The after-treatment is simple. Twelve hours after operation the patient is given sips of milk and Vichy if there is no vomiting, and in a few days is placed on regular diet. The urine is drawn till the fourth day, when the gauze is removed from the vagina. After that the patient empties her bladder, and receives a vaginal douche of sterilized water or 1 to 3,000 sublimate solution after each urination. After the removal of the gauze a small strip is introduced; this is changed in three days. Twenty-four hours after the operation the patient receives an enema of Rochelle salts, ℥ iv.; olive oil, ℥ ij.; glycerine, ℥ jss.; enema, Ojss. If this does not thoroughly empty the bowels of flatus and produce a free movement, then salines are administered by the mouth. Usually, however, the enema is sufficient.

The abdominal wound is usually dressed on the seventh day, unless there is some reason for interference. By the end of three weeks the patient is, as a rule, able to leave her bed. The vagino-abdominal method of enucleation is commended in all cases where hysterectomy is necessary for the removal of fibro-myomata, except in those cases where the tumors do not crowd into the pelvis but pull the cervix and vagina toward the upper pelvic cavity, so that the portio vaginalis can hardly be reached by the examining finger; here the whole work of enucleation must be done through the abdominal incision. The vagino-abdominal method of enucleation is to be preferred to all other methods of hysterectomy—as it is the safest and simplest; there is no danger from hemorrhage nor from sloughing, as there is no constricting of tissues by ligatures or clamps. There is no offensive septic vaginal discharge due to sloughing of the stumps in the vagina. There is no danger of tying the ureters, and the chances of injury to the bladder are very slight; shock is not so often noted, and the danger of sepsis is reduced to the minimum.

148 James Street.

ANTIPHTHISIN.[1]

By CHARLES DENISON, A.M., M.D.,

DENVER, COL.

What I know about antiphthisin I have learned since the middle of last December; and I have to thank Dr. Edwin Klebs, the author of it, and Dr. Karl von Ruck, of Asheville, N. C., for many courtesies received which enable me to make a pretty fair showing for the remedy. Yet I cannot consider the remedy as absolutely perfect, nor the technique of its administration as unquestionably determined. One ought to have a longer time of observation, and a larger series of cases from which to draw conclusions, before presenting a conclusive report. Therefore please consider this as preliminary to a finished report.

Antiphthisin is very much like tuberculocidin (Klebs), though differently prepared. Instead of being made from tuberculin, it is made directly from the ten-times-concentrated culture fluid of tubercle bacilli, the toxic principles which tuberculin contains being supposedly excluded. It is thus claimed to represent the soz-albumin—the probable germicidal property in tuberculin—as much as exists in an equal quantity of tuberculin; and its special value depends upon the fact that a larger dosage is allowable without the injurious toxic effects to be expected from large doses of tuberculin.

According to Professor Klebs "the separation of tuberculin (representing the tubercle bacillus, culture fluids, and ripe cultures) into its distinct constituents gives:

"*A. A tox-albumin*, precipitated by sodic iodide of bismuth.

"*Physiological effects*—fever, malaise, headache, general aching, nausea, diarrhœa, lung congestion, cough.

"*Therapeutic effects* in small doses—stimulant to tubercular tissue.

"*B. Alkaloids*, soluble in alcohol.

"*Physiological effects*—depression of heart and circulation, diminished arterial pressure, capillary thrombosis, hemorrhagic effusions in parenchymatous organs.

"*C. A soz-albumin* (antiphthisin).

"*Physiological effects*—none in doses up to 10 c.c.; destroys tubercle bacilli in the test-glasses.

"*Therapeutic effects* in animal experiments—confers a slight degree of immunity to tubercular infection. Causes resorption of tubercular tissue and conversion of such to the form of tissue from which it proliferated. Obtains the complete cure of 'guinea-pig tuberculosis' in the human subject. Tubercle bacilli degenerate and disappear, tubercular infiltrations are resorbed, and the consolidations clear up. Fever is diminished or disappears owing to destruction of bacilli and resorption of tubercular tissue. Secondary fever may occur, however, from its effects upon tubercular lesions.

"*D. An albuminoid substance*, obtained from the bodies of the tubercle bacilli.

"*Physiological effects* in animals—confers immunity to a much greater degree than does raw tuberculin.

"*Therapeutic effects*—not fully determined and now the subject of experiment. In the healthy human being, harmless in doses up to 3 c.c. Not yet tried in tuberculosis."

This, to my mind, is the most lucid description yet given of the ingredients of tuberculin or the combined substances from which it is made. And the separation of the "soz-albumin," if accomplished as Professor Klebs claims, entitles him to great credit; for many of my own cases seem to furnish a verification of his statement that the major part of the germicidal influence of tuberculin resides in this soz-albumin or antiphthisin.

When, last December, I was asked to give the remedy a thorough trial, I was requested by Professor Klebs "that you will not try the remedy except in cases of pure tuberculosis, and exclude from the treatment, for the present, cases of mixed infection, and septic cases, and of course all such as have amyloid or are so far reduced physically that they necessarily must die of the complications or exhaustion already present."

In regard to such exclusion I must explain that it is very hard to make it work. For instance, there are very few cases which come to a health resort like Colorado in whom there is not some "mixed infection." Therefore, as my object has been to help my patients more than to prove the uniform efficacy of the remedy, I have followed my natural inclination to give some almost hopeless invalids a chance. I conceive that the best test of a remedy is not that it will work well (as is claimed for all so-called cures, climatic or otherwise) in incipient non-febrile cases, or as usually erroneously stated, "in the first stages;" but the proper test is that it has some specific effect upon the disease as we most often find it; and that is after there has been more or less breaking down of lung tissue. Climate, with right living, can take care of those other cases, but we need a remedy which without injury to a far-gone consumptive will give him, on the lines of more or less permanent immunity to tuberculosis, the benefit of his ten to thirty per cent. chance of arresting his disease, if in fact that slim chance is his. I believe that somewhere, within the range of the remedies here discussed, that boon resides, if we can only get at it; and antiphthisin seems to be the nearest approach to it yet proposed.

[1] Report on Professor Klebs's New Tuberculin Derivative and Some of the Cases Treated.

It may here be asked, How about "the anti-tubercle serum" treatment lately introduced by Dr. Paul Paquin, of St. Louis? I have not investigated that method sufficiently to indorse it as proven, but I was present at the late meeting of the American Medical Association when Dr. Paquin presented three patients treated with his horse serum, and after the reading of his paper I invited him, as well as Dr. von Ruck, to my hotel, where for about two hours we examined these cases and their histories. Dr. von Ruck was inclined to believe the good effects noted were due to a transmitted "tuberculin effect," but I could make nothing satisfactory out of them because there was nothing corresponding with my own usual examination with which to make comparison. The original examinations and histories had been made by different interns in the hospital, and essential points were not noted and classified. For instance, there had been no attempt even to determine the daily fever range and its change under treatment. However, admitting a favorable condition of arrest, perhaps, there was no positive cure in any of these cases, for both Dr. von Ruck and I found infiltrations in all, and the evidence of softening (in progress or recent) in one. How much of the good effect was to be attributed to the horse serum alone, and how much to the supposed immunizing of it, was impossible to tell.

Last year I experimented myself somewhat with dog serum, the healthy puppy having been thoroughly treated previously with tuberculin, but I could get no certain good effect in addition to that of the tuberculin thus transmitted through the dog's blood. Afterward I inferred from evidence in Sternberg's "Bacteriology" that such an experiment as I had tried must give an uncertain result, for toxic germs sent through the circulation of an animal are variously affected according to that animal's resistance or other conditions. In fact we learn from the same authority that attenuated cultures of some germs may be re-established as to virulency by this procedure. Probably the immunity effect is an antitoxin influence created in the blood of the living subject operated upon.

As to the use of the serum from dogs previously treated with tuberculin or the culture fluids of tubercle bacilli, I have lately learned that these experiments have also been tried in Germany and no decided results were obtained. This is one of the interesting phases of this important subject which we have to acknowledge is still in a formative, undetermined stage.

To return to the consideration of antiphthisin, let us discuss its action in connection with the study of two or three cases selected from the twenty-three I have thus far had under treatment.

Case I., November 12, 1894.—C. R——, college student, aged twenty-two, from Terre Haute, Ind.; height, 6 feet; no inherited predisposition to tuberculosis, though not of strong constitution; was in college the years 1890 and 1891, but had to leave because of poor health. A year ago was treated for catarrh. Last summer and spring had a cough and yellow expectoration. Six weeks ago had pains in left chest, though not sick in bed. Yellow expectoration for a month; less now. Tubercle bacilli were found in his sputum a month ago. Arrived in Colorado three days ago, and felt some slight chest pains at this altitude. Weight in health, 165 pounds; now 155 pounds. General condition fair; pulse, 96; respiration, 20; temperature, normal; spirometrical record, 150 cubic inches, three-fourths of what it ought to be: manometer record, 65 mm.; chest expansion, 33 and 34¾ inches; right side about three-fourths and left one-fourth inch, measured separately.

Physical Examination.—Dulness at both apices, front and rear, chiefly left, with a dilatation of left main bronchus and broncho-vesicular respiration around this; also some of same sound and exaggerated whisper inner part of right mammary region. Dulness decided and pleuritic friction base of left, especially rear.

Diagnosis.—Broncho-fibro-tuberculosis with pleurisy.

Treatment.—A blood alterative (syrup of hydriodic acid), the "inhaler and exhaler," and he will go to McCoy's, over in the mountains.

April 3, 1895.—Been at McCoy's. Caught cold and was ill for two weeks last of February, with pleurisy, etc. Then picked up; weight now, 166 pounds. Looks better; coughs and raises very little. Dyspnœa less. Spirometrical record, 155 cubic inches, and manometer, 85 mm. Pulse, 92; respiration, 22, and temperature, 99¼° F., 3 P.M. Expansion, 33 and 36½ inches, a decided gain on both sides. But there is a shrunken spot below the left clavicle and almost "cracked metal" there; the broncho-vesicular respiration before noted remains. The lower left lobe has opened up somewhat, but there are mucous râles in infra-scapular region, increased on coughing, and twenty bacilli to the field are found. He has been climbing hills and taking good care of himself, yet the lung is simply opened up and tuberculosis is not eliminated. Recommend additional treatment by antiphthisin. This was commenced in about a week, and the following is the record:

April 23d.—Reached nearly three cubic centimetres antiphthisin to-day by the rectal method; no great reactions. Physical signs are better. Bacilli only four to field after treatment of nine days.

May 3d.—Reached over four cubic centimetres antiphthisin; no bacilli to field now. Semblance of cavity under left clavicle much less, lung is clearer, and the mucous râles on coughing are heard lower down in the rear of left lung. Weight, 162 pounds; looks well; can play tennis two hours a day.

May 24th.—At longer intervals worked up to over five cubic centimetres antiphthisin for the last dose to-day. Has continued to improve, and now there is no expectoration whatever. Looks and feels better. Pulse, 72; respiration, 18, and temperature normal. Spirometrical record, 160 cubic inches; manometer, 85 mm. Physical examination shows decided improvement. Positively no "cracked metal" left apex, front. Lung has cleared up nicely, and the mucous râles on coughing at base of left are not so marked, and the patient is here to verify by his good appearance his improved condition.

If we had wished for a test case for the trial of antiphthisin, we could not have done better, I judge, than to have chosen this gentleman, who if he had any "mixed infections" had eliminated the same in the mountains, and who evidently had no concealed tubercular degenerations in out-of-the-way lung spaces, undoubtedly the bane of many doubtful or poorly understood cases. The specific could only reach the source of tuberculosis in living tissues, and that, we must remember, is as far as it should be expected to reach. There being nothing further to be eliminated, and an excellent vital resistance to aid this process, the good result is easily explained, especially to one who has other evidences of the germicidal influence of antiphthisin. We do not now know how much of immunity accompanies this germicidal effect, or how it is associated with it, but it is reasonable to believe that there is something of this nature in antiphthisin, which, according to my experience, is a decided property in crude tuberculin.

I have chosen the foregoing case to show how nicely the new remedy works in pure tuberculosis, even admitting the great aid of the climate and exercise.

I choose the next case to show that a like, though not as great, care is needed in the administration of this soz-albumin as in giving the crude tuberculin considered as a tox-albumin; in other words, to show not only that every patient should be individualized, but that the effects of these remedial agents vary in different individuals, and that the amount of organic matter, even though it is weighed and definite, admitted to be in antiphthisin, is enough to give decided systemic and febrile reactions in certain cases. This is contrary to

the announcement of the new remedy, but this only militates against its use in treatment to the extent that it is not yet a means to be universally given out to everyone who takes a notion to try it. Without the precautions the inventor of it is taking in this regard there is danger enough that, through ignorant and ill-advised use, much of the odium which befell tuberculin would attach itself to antiphthisin also.

Case II., February 21, 1895.—Mr. A. C. G——, aged forty; from Palmyra, N. Y. In the commission business; married; height, 5 feet 11½ inches; no inheritance. Previous to present sickness health good, though he is of a very nervous temperament and has been much worried about business. Have never seen anyone so alarmed and discouraged because bacilli were found in his sputum, as has been done by Dr. Lobinger in this case before he consulted me.

The history is that in June, 1894, he received some hurt in his chest, followed by a cough during July, which became worse in August, and by the end of August he was expectorating yellow matter and having some night-sweats. In November he caught cold, and this was followed by profuse expectoration, though he was not at any time sick in bed. Took considerable whiskey and milk and did not lose weight. Weight now 155 pounds. Arrived in Colorado, January 7, 1895, not much appreciating the altitude. Sputum straw-colored, less than a drachm a day. Pulse, 88; respiration, 16; temperature, normal (A.M.); spirometrical record, 220 cubic inches; manometer, 50 mm.; expansion, 32½ and 35½ inches; left ½ inch less than right side.

Physical Examination.—Dulness at both apices, especially in left infra-clavicular region, below which and in left mammary region there is a broncho-vesicular respiration and some "cog-wheel" breathing. This place under left clavicle proved to be a concealed tubercular infiltration spot, which cleared out and became a small dry cavity under the treatment which followed.

February 26, 1895.—Commenced the treatment by antiphthisin hypodermically. By the time I had increased to 1 c.c. there was the distinct reaction sound, similar to the healing sound from tuberculin, in the left infra-clavicular region, following less marked reaction sounds in response to smaller doses below and to the right of this spot, also in the axillary and interscapular regions. There were also temperature rises and general reaction results in response to 1¼, 1½, and to the 2 c.c. doses, till finally his extreme susceptibility was overcome by the tolerance created to the remedy. This was, during the last of the treatment, much aided by recourse to the rectal method of administration. The record of this case goes on to state:

May 3d.—The left lung has much cleared up. The small cavity is clear and seems to have moved up underneath the clavicle and the cog-wheel respiration below has disappeared. Have had to progress very cautiously with the treatment.

May 18th.—Has reached 3 c.c. antiphthisin. Weight now 155 pounds and he looks and *is* much better. The breath sounds are good and dry—a few bronchial (?) râles in left interspinatus region on coughing; not constant, however. The cavity in top of lung has shrunken to a smaller spot underneath the centre of the clavicle, and the breathing is nearly normal over the rest of this lung.

After this the improved condition continued till the last of May, when the patient was (temporarily) discharged to go East and bring his family out to Colorado to reside. The bacilli, which had been one to four to the field in March, became "involuted," as is usual under this treatment, in April and not easily found; and in four microscopical examinations made after April 25th up to May 25th none were found.

I believe this case is in a much better condition than that of mere "arrest." There is certainly an assurance of health in the cleared-up condition of his lung, the improved state of his feelings and general health, which bespeak a degree of immunity which it is hoped will last him for some time.

The unusual local febrile and systemic reactions to antiphthisin shown in this case are to be attributed to the fact, perhaps, that the concealed condition of the tubercular spot in the top of the left lung kept up a toxic state of his blood which, in one of his extreme nervous state, made him specially susceptible to the antitoxin effect produced by the organic substance the antiphthisin undoubtedly contained. The same effects, though much less in degree, have been variously met with in other cases, when the treatment was pushed too rapidly, yet no bad effects have resulted therefrom.[1] It only goes to show that when this remedy is made perfect, and the technique of its administration determined, we will have a specific well calculated to combat tuberculosis pure and simple. The basis for this belief rests upon conclusions stated by Dr. von Ruck as follows:

"The etiological treatment of diseases caused by pathogenic micro-organisms has for its foundation the fact that specific disease germs produce substances within the infected living organisms, and also in their own culture fluids, which are inimical to their own life conditions, and that infectious diseases thus become self-limited and cultures die out before the nutrient substances are exhausted, on account of the poisoning and destruction of the disease germs themselves by their own secretions or vegetation products." It is claimed that this specific is present in antiphthisin, and that this is proved by the self-limitation of the living cultures and by "the destruction of the virulency of the tubercle bacillus by treating it with antiphthisin outside of the living organism."

Experimentally the germicidal and healing effect of antiphthisin seems to have been shown in most of the cases I have had under its influence; *i.e.*, in the lessening of the number of germs to the field found and their degenerative or incomplete forms thrown off when good-sized doses were reached, as well as in the clearing up of consolidated or infiltrated tubercular lung tissue.

Therefore, while I cannot support the claim that antiphthisin is wholly without reaction effects, and we do not yet feel quite sure of its exact constituents and their constancy; while I must differ with Dr. von Ruck in my impression that some toxins rather than "no toxins" remain, and while I think Professor Klebs is in error in placing the dose the same per rectum as when given hypodermically, when it should be much less by the latter method, yet I am glad to recognize this great advance in specific medication. This work is certainly in the right direction, and a possibility is thereby afforded us of hastening recovery through the proper method—the increase of natural resistance to tuberculosis, and thus hope is possible for some otherwise incurable cases.

As to this question of toxins, it has seemed to me that nature may have some selective power in absorbing some and not other ingredients of the remedy when given by the rectal method, and hence that method is to be preferred in very susceptible persons highly charged with the tubercular virus. In this belief Professor Klebs seems to agree, for he writes me, "We know through the labors of Brieger that the resorption of toxins is much slower than of the other albumoses."

It has seemed to me that there is a stimulating effect due to antiphthisin, and that produces an increased leucocytosis. It has lately occurred to me that a limit to the good which antiphthisin may accomplish in a given case might perhaps be assumed to have been temporarily reached when that wonderful process is

[1] Professor Klebs wishes me to add that "the fever results from the liberation of toxins within the organism, by the degeneration of the tubercle bacilli, and the resorption of the tubercular tissue."

found to be overtaxed or to have been arrested, as shown by the paucity of leucocytes, and those swollen or granular, when demonstrated by microscopic examination with high-power lenses. If this supposition is correct, it may be a greater success still is in store for us by combining or alternating with the use of antiphthisin or a similar tubercular product something else to be found which will foster or increase this fascinating leucocytosis. A case lately investigated has impressed this expectation upon my own mind.

I would have liked to have shown the helpful and encouraging results of antiphthisin used in some of the advanced third or excavation cases I have been working with, but the time limits for this paper have already been reached, and I must content myself with the general statement that under this new treatment a certain degree of immunity and prolongation of life is possible, to be added to that which this climate here offers to a properly selected proportion of even these fated invalids.

June 20, 1895.

THE PSYCHOLOGY OF NEURASTHENIA.

By W. A. McCLAIN, M.D.,

ATHENS, O.

If we look into a medical lexicon we find this term defined as "an exhaustion or deficiency of nervous force." But this very illy defines that mysterious group of symptoms and physical manifestations which go to make up the sum total of all we know of that hydra-headed monster, neurasthenia.

It is evident to all neurologists who have given this subject any careful thought that the etiology and pathology of this disease must remain to a great extent shrouded in mystery, and very little has been added to our knowledge in this direction during the past few years.

The utmost extent of our investigations in this direction can only lead us at last to that misty borderland of mind and matter. For when we speak of the exhaustion of nervous force we are at once carried back to the fountain-head of all animal life, the nerve-cells.

What is meant by nervous force? What must be diseased to produce an exhaustion of this force?

Is it possible that a degeneration of cell life in nerve or ganglion is the cause of this exhaustion? If this were true, then this force must be generated in these structures. But science has failed to show that it is produced here.

There is evidently something out and beyond these tangible structures—an unseen shadowy hand that starts this force on its journey down the highway of the nerves. And so we find that the study of the phenomena of this disease leads us into the realm of mind, and it has therefore a psychological side vastly more interesting to us than the physiological.

Neurasthenia must be studied along the same lines as other diseased conditions of the mind.

However, I am not prepared to say that in all phases of this disease the mind as a whole is diseased, but that the same agencies which produce the one are also active in producing the other.

The differentiation between this neurosis and certain conditions of the nervous system found to exist in hysteria is at times a difficult task. The literature of the subject so far has not drawn a distinct line of demarcation. And the two diseases, or conditions, are very frequently taken the one for the other.

There is no disease, however, which paralyzes so much utility, and which imposes upon the sufferer such an amount of aches and pains, real or imaginary, as is experienced by the neurasthenic. He has the discomfort of knowing also that his best friends have no sympathy for his condition, and often speak lightly of his manifold complainings.

This necessarily operates against the condition, and often the patient is led to suppress his feelings and brood over them till at last the mind—which is never stronger than its weakest part—becomes unbalanced and the patient sinks into a condition of melancholia, and suicide often closes the scene.

Dr. Brinton, in his article on nervous diseases in the lower races of mankind, observes that neurasthenia is more prevalent among those of lower stages of culture. But this position is hardly tenable and cannot be sustained by facts gained by careful observation, and I am compelled, after a thorough survey of the field of literature on this subject, coupled with an extensive observation among the uneducated in our own country, to accept the opposite theory, and the one advanced by Dr. A. D. Rockwell in his article on this subject in the *New York Medical Journal* of 1893. In fact, among all the cases of this disease which I have observed and noted during the past seven years in hospital and dispensary, and among the lower classes in general, but few typical cases of neurasthenia were ever found. But to the contrary, among the rich and well-to-do, and especially among professional men and those who belong to the higher walks of life, this disease is more often found in its most typical form.

Dr. Brinton, as quoted by Dr. Rockwell, states that civilization, so far from increasing this malady, is one of the most efficient agents in reducing it in frequency and severity, especially when freed from "competitive anxieties."

It seems well that he added this latter phrase, for it certainly follows, from what we do know of the pathology of this disease, that these very "competitive anxieties" which are so intensified in this country—this worry of business and professional life—civilization only fosters and deepens. Perhaps no other country on the face of the globe to-day is in such a state of business ebullition—such push and excitement bordering on frenzy to outstrip all competition—as is observed in the United States. And to this state of excitement and brain fag and nervous strain, more than to all other conditions combined, is due the prevalence of neurasthenia in this country. The younger generations in most of the older countries—Germany, for instance—are content to follow in the footsteps of their fathers, and their work has a tendency to partake something of the quietude of their old hills and streams.

We seldom or never hear of English or German nervousness as the same term is applied to this country, for in this connection it carries with it a meaning of peculiar significance. It has also been observed that this condition is not found among the inhabitants of the colder latitudes. Neither is it so prevalent in the torrid zone, but only in that region known as the temperate zone, where the climate is ever changing, and the atmosphere is filled with ozone sufficient to produce a general buoyancy to the spirits. Just what this peculiar electrical condition has to do with the disease we are not yet prepared to say. But it is evident that this surplus energy, whatever may be its source, constitutes the disease proper, and not therefore a lack of nerve force as the books define it.

To use a patient's own words who was a sufferer from this disease, "I felt all the while as though some shock would cause me to explode." Is this a condition of exhaustion of nervous energy? Not at all, but rather a weakening of the lines that carry this force—a broken wire, an interrupted current, a multiplicity of currents meeting and crossing, the weaker ones being attracted by the stronger ones and conducted into unaccustomed channels, and the impression often wholly lost.

And this accounts for the inability of the neurasthenic to engage in any line of continued thought. He loses the subject and wanders, or the current of thought ceases to flow and the stream is lost in the sand.

To understand this more fully we have only to study closely the minute anatomy of the brain and its psychological functions.

That the feelings are closely connected with physical manifestations is patent and undeniable. But thought is at times so quiet, so far removed from bodily demonstration, that we might suppose it conducted in a region of pure spirit—merely imparting its conclusions through a material intervention. Unfortunately for this supposition, the fact is now generally admitted that thought exhausts the nervous substance as surely as walking exhausts the muscles.

Our physical framework is involved with thought no less decidedly than with feeling. To all varieties of human feeling there correspond varieties of diffusion in the brain, as there correspond varieties in external manifestation.

The outward signs are only a small part of the wave of effects upon muscles and viscera. Many movements receive only an incipient stimulus, too weak for producing action. The impulse in many instances may be sufficiently strong in the start, but the counter-impulse which the wave meets on its journey may be sufficient to suppress it, or to render the thought as to effect of no purpose.

But these diffused waves of nervous energy are inseparable adjuncts of feeling.

The powers of the nervous system are various, and even mutually opposed. Intellectual feebleness, decay of memory, and incapability of thought are not painful in themselves. But there is probably a distinct power of the nervous system connected with the pleasurable tone of the mind, which may not fail when intellect fails, or may fail while the intellect is yet vigorous—a function very unequally manifested in different individuals.

The mental effect of diminished power in various organic functions is ultimately realized by some failure in the brain itself. Could we suppose the brain to maintain all its functions, derangements might occur in other organs without depressing the mind, but, strictly speaking, this is an impossible occurrence. There is sometimes an approach to this situation, namely, when the blood, such as it is, flows in excess to the brain, supporting its powers at the expense of all other interests, an arrangement that cannot be permanent. In such a contingency there is an extraordinary exaltation of mental function, including a hilarious and even ecstatic enjoyment. It is the state that narcotics may produce for a brief moment in a constitution partially wrecked, and it occasionally occurs in the closing hours of life.

The neurasthenic state is not infrequently produced by causes which may be easily discerned and by treatment removed. Many of the disturbances of the digestive function, anæmia, uterine displacements, tapeworm, all are known to have produced manifestations of this disease; yet with the removal of the cause the symptoms disappeared.

But with grave neurasthenia we have another picture presented, with no objective point to be found, no tangible ground in view. We seek in vain, in the words of Shakespeare, "for the cause of this effect, or rather say the cause of this defect, for this effect defective comes by cause."

The therapeutics of this disease, contrary to most diseased conditions, is far in advance of the etiology and pathology. It is amenable to treatment, and in most cases is a self-limited disease.

Therefore the treatment resolves itself into an effort to treat the individual and not the disease; salt-water baths, a change of climate and of environment, and a calming of the surging waves of thought which dash down the interrupted channels of their being. Restrict, as far as possible, all impressions made upon the mind from without, for while we go the round of the mental circle of sensation, emotion, and thought, there is an unbroken physical circle of effects. It would be incompatible with all we know of cerebral action to suppose that the physical chain ends abruptly in a physical void, occupied by an immaterial substance, which immaterial substance, after working alone, imparts its results to the outer edge of the physical break, and determines the active response—two shores of the material, with an intervening ocean of the immaterial. There is, in fact, no rupture of nervous continuity.

And by thus studying the relation of mind and body we may yet arrive at the true pathology of this disease. When we can know and understand the origin of a thought, and the molecular change of gray matter in the brain consequent upon that thought, then, and not till then, may the pathology of neurasthenia be written.

Coming now to the medicinal treatment of this disorder, we have the whole pharmacopœia of tonics and sedatives to select from, but each case must be treated upon its individual conditions—supporting treatment consisting in good feeding; tonics, such as iron, quinia, and strychnia; occasional warm baths with massage; stimulants cautiously used, and possibly tonic doses of opium.

Usually, we may infer that the pathological condition is most likely to be one of defective nutrition from anæmia and exhaustion.

Where there are decided evidences of vaso-motor spasm of the cerebral vessels, as shown by pallor, coldness of head and extremities, tinnitus, vertigo, etc., the inhalation of nitrite of amyl is generally recommended with good results. If a more continued effect is desired, nitro-glycerine internally, one-drop doses of a one per cent. solution, is employed and cautiously increased.

These drugs seem to have a double beneficial action in these cases, dilating the peripheral blood-vessels and strengthening and freeing the heart's action, which is embarrassed by under-innervation or over-inhibition.

Alcohol and opium are the other two remedies generally recommended. I have seen some temporary good results from a single large dose of alcohol, but I am not prepared to recommend it. Its continued use is open to serious objection, and the same may be said of opium. I have never seen the opium habit created by the medical use of this drug in these cases, but I can readily see how this might occur.

Alcohol as a vaso-dilator, in the stricter sense of the term, has but a limited field of usefulness. With opium the case is somewhat different. It possibly has, in many instances, a favorable action on the blood-vessels of the brain, relieving the vaso-motor spasm and aiding in bringing about a more normal condition of the nutrition of nerve elements. In these conditions small doses seem best, from two to six drops of the deodorized tincture three hours apart being sufficient, and its results cautiously watched.

Naturally following the medical treatment of the disturbance of the cerebral circulation comes that of the management of the excessive motor excitement and irritability, one of the most prominent symptoms of this disease.

This involves the whole question as to the use of sedatives in mental disorders, in regard to which a wide difference of opinion exists among authorities, and certainly a very wide range of variation in practice.

The fact that motor activity is not injurious, but positively beneficial and compensatory, does not destroy the other fact, that in many cases it is so excessive as to wear out the patient unless checked; and the only way this can be done successfully is by the use of sedatives. And possibly the safest of all these are the bromides of potassium and soda. They seldom do harm when properly diluted, and they are excellent adjuvants to other and more powerful quieting agents.

Clouston recommends the use of the bromides with cannabis indica as the best general sedative, while others claim that Squibb's fluid extract of conium and hy-

oscyamus with ten to fifteen grains of chloral is the best all-round sedative for these conditions.

But the tonic treatment must not be lost sight of for a moment. Maltine, cod-liver oil, the peptones, acid phosphates, all have a decidedly beneficial action on this disease, and on most mental disorders. The faradic or galvanic current is of doubtful utility. But the Weir Mitchell treatment and abundance of fresh air and sunshine, promise more relief to these most miserable of all human sufferers—the neurasthenic.

ARE WE LIKELY TO HAVE ANY MORE EPIDEMICS OF ASIATIC CHOLERA IN NEW YORK?

By F. A. BURRALL, M.D.,

NEW YORK.

During the last few years much anxiety has been felt lest cholera, which was then a wide-spread epidemic in Europe, should cross the sea and again visit this country. The painful memories of former visitations are not yet effaced, and it was with a sense of relief that summers were seen to pass and cool autumns arrive, without the advent of the Asiatic scourge.

It is reasonable to suppose that until sanitary regulations are better enforced and ignorance is less prevalent in some portions of Russia and the East such menacings of cholera will be likely to recur.

The question arises, How far should they be a source of anxiety to this outpost of our country, which has often been a distributer of this pestilence? Have any advances been secured in the knowledge of cholera during later years which render it more manageable than formerly and less an object of dread? The study of this question is connected with the history of the Asiatic scourge.

The literature of the subject is so extensive and complete that the materials for such a study are very ample. Its peculiar features have attracted the careful scrutiny of the keenest and most patient medical observers, and page after page bears witness to the untiring efforts which have been made to solve the riddle of this erratic and mysterious pestilence. In looking through the literature of cholera we can clearly follow the forward and backward footsteps of the trail which have at least arrived at definite opinions. These views, based on the most laborious studies and scientific investigations, explain why cholera has been so difficult to control and so destructive to human life. For a long time the views concerning its origin and nature were indefinite and conflicting. Now vague, now fanciful in the highest degree,

> "Such stuff as dreams are made of,"

this did not interfere with the tenacity of those who held them, and the result was to render any unanimity of action which looked toward preventive measures weak and futile. Such unanimity was absolutely necessary for practical results.

For a long time the question of the communicability of the disease was completely unsettled. Those who studied the pestilence and even treated it in epidemics were widely at variance concerning this point. It is difficult for those of us who have watched the rise and establishment of the modern ideas concerning cholera to understand how men could have failed to see the bearing of facts which now lie so open and clear to the view. Yet, as in other matters, the strength of preconceived opinions is often so strong that facts are forced as far as possible to fit these opinions, and the plain, obvious truth is overlooked. Such views as these of Jameson, who wrote in 1855, are an instance of the ideas of very many at that period. He writes:

"Everything, we think, conspires to disprove the belief that the cholera poison came from the East, traversed parts of Europe, and then arrived in this country and now fills a considerable part of this continent. Since we have no control over this specific matter, it is not very material whether we can or not ascertain its source, but we think, with Sydenham, that its primary cause emanates from the earth. In briefly summing up the character of cholera, we view it as an epidemic and of course dependent upon some atmospherical contamination for its predisponent cause, mostly confined to neighborhoods of moderate extent, but sometimes, simultaneously or in near succession, in different places; it is most clearly non-contagious, non-migratory."

Still another writer gives it as his opinion that "I wish it to be distinctly understood that I have seen nothing in its progress that has led me to conclude that contagion is instrumental in its diffusion. One or two *prima facie* cases of infection have presented themselves, but a little scrutiny has shown me their fallacy."

As to the cause of cholera, all kinds of ideas were advanced. One writer is of opinion that the disease depends upon a "subtle entity," which spreads by the agency of some modification of electricity, like ozone. He writes:

"What other agent is there to which we could ascribe the appearance of cholera in its course? It is true, electricity has the quality of ubiquity, but this does not interfere with its change of place, as may be seen in the operation of the telegraph. All the known laws of electricity, in all its modifications, serve to give it fitness for the agency of spreading a subtle entity, like the entity which gives rise to cholera."

In 1866, among other views which were brought forward to explain the cause of cholera, it was reported by "Malakoff," who was then the Paris correspondent of the *New York Times*, that "a distinguished lady of title had made a communication to the French Academy of Sciences, that she had discovered the cause of cholera in a microscopic insect which she calls the winged leech and which she says is developed in marshes and filthy localities. The details she gives in relation to the animalcule and its connection with cholera are so minute that the Academy, which commenced by laughing at the first paragraph of the report, finished by deciding to investigate the matter."

It was hunting in the fog to seek for prevention, while the nature of the disease was so imperfectly understood and its communicability denied. Far-fetched explanations were advanced for the strange conduct of what seemed to be a capricious pest, and the opposing views held by those who had had the best opportunities for studying the disease led physicians and the public to regard the new theories with scant favor.

The belief in the communicability of cholera had been making slow headway for years. The admission of negative evidence was a great impediment to its progress. But those who thought cholera communicable held that the testimony of the five witnesses who saw the culprit steal the axe was not at all weakened by that of the twenty who swore that they did not see the theft. There were so many instances where the arrival of cholera patients at villages or in families in which there was no cholera, was speedily followed by an outbreak of the disease, that these accumulating facts bore convincing evidence in favor of communicability. Why, as was the case, should cholera appear in an uninfected island of the ocean, soon after the advent of a vessel with cholera on board, unless it had been brought there by that vessel? One such instance of portability would be insufficient as a ground for belief, but the facts flowed in in increasing numbers, and from 1867 to 1870 the doctrine of the communicability of cholera had gained a hold sufficiently strong to form a basis for definite sanitary action. The settling of this point in the minds of the majority

was the most important step in advance which had been made for years. In this light was explained the strange circumstance, which had seemed inexplicable, that this pestilence had attacked ships in midocean as if borne from distant lands or dropped from the clouds, by attributing it to an infection caused by the opening of trunks and airing of infected clothing by passengers from infected districts. It may be incidentally mentioned that cholera has been said to be unaffected by cold, and to spread even in spite of the rigors of a Russian winter. A satisfactory explanation of this fact seems to be that the houses of the poorer Russians are closely sealed to keep out the intense cold. The interior is hot and filthy, and thus the cholera plant is fostered and carried from house to house, although it would die in the temperature of the external air. At present it is established that great cold is unfavorable to the spread of this disease, but at one time, before the communicability of cholera was admitted, the spread of a winter epidemic was regarded as another *bizarrerie* of this inscrutable plague.

Communicability having been admitted, or in other words the transfer of the disease as a special poison by human agency, then the question of prevention assumed a more definite and practical form. Prevention was all the more important, since the treatment of the fully developed malady was and still is extremely unsatisfactory. The mortality remained about the same, notwithstanding that one treatment after another was recommended, as new epidemics came and went. A certain number of the sick recovered under almost any treatment. Methods of cure which seemed effective in one epidemic proved valueless in another, and in estimating the effect of remedies it was necessary to take into account the period of the epidemic in which they had been tried, since the mortality in the early part of the epidemic was found to be naturally much larger than in the later portions. On the other hand the treatment of the premonitory symptoms of cholera had been found quite efficacious, and general cleanliness had limited to a certain degree the large mortality.

As confidence became developed in the efficacy of preventive methods, these methods were more carefully studied and improved. Isolation, cleanliness, the use of pure water, and house-to-house visitations were found to be of use, because definitely directed against a special poison, which displayed prominent characteristics, although its essential nature was still unknown. The great mistake which had been made, of concealing or denying first cases of the disease for fear of creating a panic, seemed but natural when no satisfactory method of treating them was known. While the cases were being discussed, the disease spread, and as in one of the Parisian epidemics, where the pestilence broke out in vast proportions, this was not a primary wave, but the sudden development from cases which had been present in the city for a month.

Confidence in the power of prevention has also led to another and most important step which is strongly in contrast with previous custom. Doubtful cases are treated with all the sanitary discipline of genuine cholera, and efforts are made to bring to the light all such, in order that a possible lurking evil may be "stamped out" before it has made headway.

The discovery of the cholera germ by Koch has thus far been of less practical value than of interest from a scientific point of view. This statement is for the present time: If anti-cholera inoculation should prove successful it will be the great preventive method, but this treatment is still *sub judice*. At all events, the discovery of the bacillus was a most important link in the history of the disease and most essential to its completeness. Still what had already been acquired was directly in the line of what would be indicated by that discovery. It has often been the case that medical treatment has been in advance of that more exact scientific knowledge which comes later to justify the treatment and explain its results.

One fundamental consideration which precedes all others when we regard our liability to an introduction of cholera is our separation from European ports by the ocean. It is only from those ports that we have ever received it. The shortest voyage across the sea is longer than the ordinary time which elapses between infection and the appearance of choleraic symptoms. The question is not fully settled, but it must be admitted that the usual period of incubation is within four or five days. A maximum period has been placed at twenty-one days, but if we consider the very great infrequency of cases upon which this estimate is based, we must admit the possibility, at least, that the infection came from soiled clothing or fomites, to the poisonous action of which the patient had been exposed during the latter portion of the twenty-one days.

We may now ask what legacy have the years given us after all the suffering and experience and study which have accompanied the successive epidemics of cholera?

It cannot be claimed that our knowledge of cholera is complete. In some directions we have only a "working hypothesis," but the knowledge acquired is sufficient to form a good basis for preventive treatment.

We may regard it as a standard opinion at present that Asiatic cholera is a disease produced by the fermentative results connected with the presence of the cholera bacillus. The existence and growth of the bacillus are favored by certain conditions, while interfered with, even to annihilation, by others. Intense cold checks its growth, many chemical agents destroy it, cleanliness retards its advance. Experiments[1] made to ascertain whether the soil in itself has any action favorable or injurious to the comma bacillus of Asiatic cholera, apart from the moisture which these soils contain, are of much interest. The earth experimented with was white crystal sand, yellow sand, garden earth, and peat, and these earths were sterilized by moist heat. Under these circumstances the bacilli in these different soils died between the third and fourth day. In a moist soil, where there was no excess of moisture, it was found that the bacillus in the white crystal sand was alive on the seventh day, in moist yellow sand on the thirty-third, and in moist garden earth also on the thirty-third day. Peat was unfavorable to its vitality, since in that soil the bacilli were dead in from invariably twenty-four to twenty-six hours, independently of the amount of moisture present. Whether the acid present in peat is inimical to the bacillus is not stated. Some acids, such as sulphuric, have been supposed to act as antidotes to the poison of cholera. It has long been held by Pettenkofer that the epidemics of cholera depend for their prevalence on the varying quantity of water in the soil, and in India certain places, like Multan, in the Punjaub, are considered as out of the cholera area, and cholera is "always present in damp Bengal." So that the drift of evidence indicates that moist soils favor and dry soils impede the spread of this pestilence.

Cholera is not regarded as contagious in the exact sense of the word, but the germ taken within the body, as by food or water, originates the disease, and this is spread by the fermented waste of the body.

The usual period of incubation is placed at from three to four days. The occurrence of those longer periods which are given as elapsing between exposure and the appearance of symptoms may be explained by attributing them to infected clothing or other fomites.

As a rule, epidemics in this country begin by a single case, or two or three in near succession. The premonitory symptoms of cholera are, as a rule, easily controlled. A quarantine may be so conducted as to aid very de-

[1] London Letter to the New York MEDICAL RECORD, June 23, 1895.

cidedly in prevention without greatly embarrassing the demands of commerce.

What, then, do these premises indicate with reference to systematic effort in keeping cholera out of this continent, and especially New York? In the first place, such an examination and preliminary quarantine as was practised on immigrants sailing to America from Amsterdam or Rotterdam during recent cholera epidemics was a defensive blow nearest the seat of the evil, and a five days' quarantine, with airing or disinfection of clothing, would be a great advance on former methods.

A second quarantine on this side of the water, in the event of suspicious cases arriving on board of a vessel, is an additional defence. If thorough disinfection of personal clothing and baggage is practised, and all exposed localities are carefully cleansed, so that if the disease enter it may find no soil to nourish it, it does not seem necessary to require a detention longer than ten days, including the passage, for healthy vessels from infected ports or which contain passengers from infected districts, or for infected vessels of more than ten days after the end of the last case of cholera or acute intestinal disturbance.

The thorough cleaning of seaport towns, and a supply of pure drinking-water.

The co-operation of the community with the authorities in reporting all suspicious cases. No one can be "frightened into cholera" if the specific disease does not exist, and the best method of averting it is, with confidence in our present preventive agencies, to search out and destroy the earliest sparks of the fire before it goes beyond our control.

The sanitary treatment of all doubtful cases as if they were genuine, with the same aids of isolation and disinfection as are used at present so successfully in our epidemics of scarlet fever, diphtheria, measles, and small-pox.

In this article are contrasted the former views concerning the nature of Asiatic cholera with our present standard opinions and the views concerning preventive treatment. A comparison of the earlier with late views shows us how high the tide has risen. The results of preventive efforts made within a few years in this city are full of encouragement. We cannot tell how many more threatenings of cholera we may have, but it does not seem probable that this city will ever again be forced to lament the visitation of a cholera epidemic. It would seem as if nothing but a relaxation of our present vigilance could account for such an unhappy event.

What this means in the establishment of that calm confidence which soothes and upholds the nervous system of a community, as opposed to the effects caused by the dread of a coming horror, what of sorrow and misery would be averted, what of business complications and loss of treasure would be avoided, it is impossible to thoroughly comprehend in all painful detail.

The Duke of Cambridge seems to be a cad. He is commander-in-chief of the British army and is about as well qualified for the position he holds as was the ruler of the Queen's Navee; yet he had the impudence to refer to Surgeon-Major Robertson, who distinguished himself for heroism at Chitral, as "that brave civilian," not recognizing a surgeon as an army officer. Surgeon-Major Robertson is to be congratulated in not being recognized as a comrade of the absurd Duke of Cambridge.

The Horse is in Luck, for just at the time that his occupation as a drawer is in danger of being lost in competition with electricity and the bicycle, the antitoxin treatment has created a demand for him as a purveyor of serum.

FRIEDREICH'S ATAXIA, WITH CASES.[1]

By SIDNEY I. SMALL, M.D.,

SAGINAW, MICH.

In reporting these cases of this comparatively rare disease I do not expect to add anything original to its literature, but I am encouraged to believe that a history of the cases which have been under my observation for a considerable time, illustrated by the presence of the individuals themselves, will be of sufficient interest to claim a small share of the Society's time.

I trust it will not be deemed a reflection on the dignity and erudition of this Society that, before taking up the personal histories, I recite briefly the history and general course of the disease, as a reminder for those who have had no special reason for its recent study, and an aid to the appreciation of the symptoms as they appear in the different stages.

The disease was first noticed in 1861, by Professor Friedreich, of Heidelberg, who at that time reported six cases. In 1866 but 14 new cases had been reported. In 1872, the number had increased to 47, and at the present time is something over 200. The only case which has been reported in this State was described by one of our own members, Dr. Inglis, in a paper read before this Society in 1891.

For a definition of the affection I shall quote from the excellent monograph of Dr. J. P. Crozer Griffith, as giving briefly, and yet clearly, the results of study up to the present time:

"Friedreich's ataxia is a chronic systemic inflammatory degeneration of the spinal cord, developing usually in infancy or childhood, and occurring in cases in which there has probably been an arrest of development of the cord during fœtal life, this being the result of some hereditary predisposition. It is situated chiefly in the posterior columns, the lateral pyramidal tracts, the direct cerebellar tracts, and the columns of Clarke, though other parts of the white and gray matter are very commonly somewhat affected, and the sclerosis extends slightly into the medulla. The affection is characterized clinically by a disturbance of the co-ordination of the bodily movements, developing gradually, advancing from below upward, and finally involving the organs of speech. Curvature of the spine, talipes, vertigo, and nystagmus are frequent. The patellar reflex is nearly always abolished. Paralysis and sensory disturbances are not uncommon in advanced cases. Trophic, vaso-motor, and visceral affections are unusual, and any involvement of the intellect is probably accidental."

It is probable that all sufferers from the disease inherit from some of their ancestors, near or remote, a tendency to degenerative processes, yet to call it hereditary we must regard the term in its broadest sense. While cases are recorded of undoubted direct or similar inheritance, in the large majority it will be found that the ancestors suffered from some other form of nervous disease; and a certain number appear in which no sign of heredity has been discovered.

But few well-marked cases have shown the first symptoms after the age of twenty years. In 127 cases tabulated by Griffith, the first symptoms were noticed in 39 before the age of six years; in 45 at from six to ten years; in 20 at from eleven to fifteen years; in 18 at from sixteen to twenty years; and in 5 at from twenty to twenty-five years. Not infrequently the first manifestations of the disease have been preceded by some acute affection, usually infectious.

Clinically, Friedreich's ataxia resembles tabes dorsalis and disseminated sclerosis. In our diagnosis we have to bear in mind the early development of Friedreich's disease, its slow but steady progress, its tendency to occur in several members of the same family, the peculiar oscillating, staggering gait, the usual absence of the patellar reflex, the deformity of the feet,

[1] Read before the Michigan State Medical Society, June 7, 1895.

the slow, thick speech, scoliosis, and nystagmus; the absence of pain, cerebral disturbances, and genito-urinary troubles. Tabes dorsalis is a disease of adult life, with pain as an early and common symptom, seldom affecting more than one in a family; lesions of the optic nerve are early and frequent symptoms, without curvature of the spine, or inco-ordinations of speech, and very seldom nystagmus.

Disseminated sclerosis rarely appears before the age of twenty. The onset is sudden, and but one case in a family affected. There is exaggeration of tendon reflexes, spastic paraplegia, cerebral disturbances, with vertigo, headache, and epileptiform and apoplectiform attacks. The general pathological changes are well described in the definition quoted at the beginning.

Three of the cases which form the subject of this paper have been, for a number of years, inmates of St. Mary's Hospital, in Saginaw. The fourth is living in Essexville, in which town all the children were born.

In my study of the family history I find nothing of importance on the paternal side. The father was a native of Holland, and came to this country at the age of twenty-five. He was a large, strong man, and healthy until a few years before his death, which occurred at the age of sixty-one, of gastric cancer. His father and mother died in Holland at the age of fifty-eight and fifty-two, respectively. One brother is living in this State at an advanced age.

The mother of the patients, French, a native of Canada, died at thirty-eight years of age from blood-poisoning, the result of vaccination. Maternal grandfather living at eighty-five; maternal grandmother died at seventy-three. A sister aged twenty-eight is in good health, and a brother aged sixteen is apparently well, though inclined to stammer, especially if at all excited, and the patellar reflex is absent or doubtful.

From a maternal aunt I obtain the following personal history: She is forty-six years of age, and has been married twenty-three years. Three months after marriage, being then pregnant, she took cold, and had "inflammation of the lungs" which lasted several months, and for one year after recovering from this illness she was unable to walk, and had no sensation in her legs; then she learned to walk as a child learns. Three years afterward, in her third pregnancy, she suffered an attack similar to the former, and was again unable to walk for a period of a year and a half, since which time she has been well; so she says, but when the marked kyphosis of the dorsal region developed I was unable to elicit; probably at the time of her first illness. She has had nine children, seven of whom are living. The first-born died at two and a half years of age, never having been healthy, though I was unable to learn the immediate cause of death. The other died of diphtheria. The remaining children are well, mentally and physically. A cousin of the parents on the mother's side has a daughter eight years of age, who has since the age of eight months had convulsions, and is still an infant in all but years. Three other children, of the ages of four, six, and fourteen, are in good condition, physically and mentally. It may be worthy of note that the parents are slightly related—their grandmothers being half-sisters.

In another branch of the family is a girl, eleven years of age, a distant cousin of the patients, who had hemiplegia in infancy, and still remains weak in body and mind. Eight other children, whose ages range from eight to twenty-two years, are in good health.

The following personal histories are obtained from the patients themselves and their friends:

Case I.—Mary V——, aged twenty-six. She was in good health up to thirteen years of age, when there appeared an unsteadiness in her gait—a wavering, uncertain manner of walking, with frequent falls. The patient says there was an uneasy sensation in the back, and later in the knees and ankles, though it never amounted to absolute pain. She also remembers that she was unable to stand upon a chair, or anything raised even but a little distance above the ground, and this she noticed some time—four or five years—before the trouble in walking appeared. At the age of nineteen, the difficulty in walking had so far increased that she was compelled to use crutches, and after about four months was no longer able to walk even with this support. Menstruation began at eighteen, and has been normal.

Present Condition.—The patient sits during the day in an arm-chair in a somewhat stooping or rather slouching position. There is some scoliosis in the dorsal region. She is unable to walk or stand, and gets about by drawing herself along the floor by the hands. With difficulty she can get from the floor to a chair. She can extend and flex the leg upon the thigh, but cannot flex the thigh upon the trunk. The feet are in the condition of talipes equinus, with a tendency to dorsal flexion of the great toe. Patellar reflex is absent or doubtful. There is no more atrophy of the muscles than would naturally follow disuse. The muscles of the arms and hands are fairly strong, but showing marked inco-ordination. An attempt to bring the forefingers together, or to touch the tip of the nose or the ear is seldom successful. When the limbs have remained for some time at rest the patient is unable to tell their position except by sight.

In grasping an object the hand and fingers are held in a claw-like way, and often carried beyond and about the object before seizing it. The functions of the bladder and rectum are normal. The speech is thick, as though some object were held in the mouth, and the words are pronounced in a slow and somewhat jerky manner. Though generally of a quiet and serious habit, the patient is subject to fits of immoderate and uncontrollable laughter on slight provocation. There is no impairment of intellect or memory.

Case II.—Joseph V——, aged twenty-five. Ataxic symptoms first noticed at the age of thirteen, but he was able to go about and work until the age of eighteen, when he had what seems to have been an attack of typhoid fever, lasting seven weeks, and after recovery he could walk only with the aid of crutches, and this aid soon became insufficient, and walking impossible.

Present Condition.—He is unable to walk or stand, and with great difficulty gets from the floor to a chair; and yet he goes down several flights of stairs, out of doors, and about the lawn, sliding down the stairs, and returning very slowly by seizing the balusters with his hands and drawing himself up a step at a time. His method of locomotion is the same as that of his sister, drawing himself by the hands.

There is scoliosis in the dorsal region. He can extend and flex the legs, and flex the thigh upon the trunk. The same condition of talipes and dorsal flexion of the great toe is present, as in his sister. The patellar reflex is absent; the plantar reflex well marked. There is no apparent lack of strength in the muscles of the arm and hand, but the inco-ordination is much greater than in the case of his sister; and there is the same inability to locate the position of the limbs when at rest. There is no affection of the visceral or urinary organs. There is a slight oscillation of the head, which is increased by conversation or excitement. The speech is slow and even more unsteady than in the previous case.

Memory and intellect unimpaired.

Case III.—John V——, aged twenty-four. The first symptoms appeared at the age of thirteen, gradually increasing, and at the age of twenty-one he gave up walking altogether, after a few months' use of crutches. No illness preceded and no pain accompanied the ataxia. One bit of information which he gives concerning his childhood tells of inco-ordination in the arms at an earlier relative date than is usually given. He could not drive a nail or use a hammer at

all successfully, but always hit something different from that at which he aimed.

Present Condition.—Much the same as his brother, except in degree, the symptoms being slightly less marked, as might be expected from the difference in duration; and both patellar and plantar reflexes are present.

Case IV.—Julia V——, aged twenty-two, was in good health previous to the first appearance of the difficulty in walking, at the age of fourteen. Never had any pain—not even a headache, and even now, when sitting in a chair, feels as though she could get up and walk as well as anyone. Menstruation began at eighteen, and has been normal.

Present Condition.—She has a healthy appearance and intelligent expression. She walks only by the aid of a chair, but is constantly engaged in work about the house, and happiest when she is busy. The ataxia is greater in the right leg. In both feet, but more marked in the right, is a condition of talipes, or rather an appearance of exaggeration in the arch of the foot at the expense of its length. This is more noticeable than in any of the others. The patellar reflex is absent, plantar reflex normal.

A point which I have noticed in all of these cases is a tendency to hyper-extension of the thumbs.

In no one of them has there been pain, anæsthesia, or girdle sensation, and nystagmus has not appeared as a prominent symptom.

An examination of the eyes in Cases I., II., and III., by Dr. D. B. Cornell, discovers some atrophy of the optic nerve. Accommodation, pupillary reflex, and color sense are normal.

Progress of Medical Science.

Combinations of Morbid Conditions of the Chest.—Dr. F. T. Roberts, in his Lettsomian Lectures on this subject, easily makes good his contention that such combinations are very common and that their importance and significance are inadequately recognized. The error of fixing the attention upon one morbid state or one prominent clinical symptom is very general, and to immature minds and unskilled observers is practically irresistible; but we all need occasional reminders that there are no hard-and-fast lines in nature, and that the elaborate classifications and hard-and-fast distinctions so usual in text-books, though often practically useful, give an erroneous impression of a fixity and precision which as a matter of fact do not exist. (*The Lancet.*) Disease is not mathematical or mechanical. It is fluid, mobile, easily passing from one transition to another, incapable of precise definition, obeying general laws and definite principles, but not to be confined within the limits of rigid rules or unvarying formulæ. Specialism in medicine is always open to the reproach that disease refuses to recognize the limits of the specialist's domain. Dr. Roberts wishes to utter "an emphatic protest against the absurd development of specialism in relation to this region—*i.e.*, the chest—which at the present day is working so much mischief;" and he gives it as his opinion that "the practice of dealing with each thoracic organ as if it were entirely separate and distinct, or, still more, of making a specialty of different complaints, is both dangerous and absurd." It is evident, we think, that any attempt to study pulmonary disease apart from morbid conditions of the heart must be doomed to failure; and to this extent, at all events, we entirely concur in Dr. Roberts's *caveat* against excessive specialism. But we must beware of running from one extreme to another. Dr. Roberts discusses a group of cases characterized by a combination of conditions difficult to define, but of great practical importance. "In these cases the superficial structures are more or less wasted, it may be considerably; the chest-walls are obviously rigid; localized pleuritic adhesions can be made out, it may be in several spots; there are no gross lesions to be detected in the lungs, but these organs are evidently wanting in normal elasticity and tending toward degeneration, perhaps also exhibiting limited areas of emphysema, or there is a suspicion of a fibrotic change here or there; sometimes there are indications of commencing atheroma of the aorta, or the heart is feeble in its action and is probably of actually small size." Everyone is familiar with these cases which, as the lecturer says, do not belong to the chronic emphysematous or phthisical groups, and are often, for want of a better title, simply labelled cases of "weak chest." The important practical point about such cases is that they do well by using suitable precautions and having an occasional change of climate; but that even a slight bronchial attack is a serious matter for them and that they die really from pneumonia or other grave acute affection. The prognosis and treatment of such cases require to be regulated by a due recognition of the fact that symptoms trivial in themselves acquire a serious gravity when viewed in relation to this peculiar type of patient. Dr. Roberts protests against the crude and superficial way in which many of the laity talk of phthisis, as if the mere recognition of the bacillus explained everything. He points out the absolute necessity of recognizing the numerous grave organic changes wrought by the disease, such as consolidations, tuberculous, inflammatory, caseous, or mixed; miliary tubercles, diffused or in groups; softening of these structures; cavities, reparative changes, the formation of fibroid tissue, bronchial inflammation, compensatory emphysema, and the like. Cases of chronic pneumonia, in whatever way arising, "in time assume a decidedly complex character. The fibroid change is limited in most cases mainly or entirely to one lung, or a portion of it, which is thus hardened and contracted, the involved structures being rendered quite useless; it is often accompanied with the remains of phthisical cavities, and still more frequently with dilated bronchi, while unaffected areas of the same lung, as well as the opposite one, become the seat of compensatory distention, which may ultimately terminate in true emphysema. . . . There is an exceptional class of chronic pneumonic cases which may prove very puzzling. In these one lung is absolutely solid, either throughout or over a large extent, but instead of being contracted it is more or less enlarged. The opposite lung becomes greatly distended, and also in some instances the seat of dry bronchial catarrh; so that the general aspect of the patient, as well as the prominent symptoms, may resemble closely at first sight those of an extreme case of emphysema and bronchitis, with an asthmatic tendency." Asthma and angina pectoris afford Dr. Roberts good instances of the necessity of a comprehensive view of chest ailments. In a large majority of cases asthma "supervenes upon distinct and obvious morbid changes associated with the chest, which tend to become more and more pronounced as the case progresses. The cases in which asthma occurs are usually more or less of the emphysematous and bronchitic type; but rigidity of the chest-walls, adhesion of the upper part of the lung, and other factors, are often of much importance in these cases in relation to asthmatic attacks." Angina pectoris "usually complicates more or less definite morbid conditions of an organic nature. . . . Those which are most likely to be overlooked are atheroma or calcification of the aorta and coronary arteries, and cardiac degeneration not of a pronounced character." Dr. Roberts is emphatic on the importance of recognizing what may fairly be expected from treatment and what it is folly to attempt; on the necessity of wisely adapting our measures to acute conditions supervening on chronic; on the need of grappling promptly with grave conditions readily

amenable to treatment—*e.g.*, effusions into serous cavities; on the value of rest and the simpler drugs; on the impolicy of fussy therapeutics and routine symptomatic treatment; and on the wisdom of being on our guard in relation to new "cures" and vaunted specifics.

The Importance of Menstruation in Determining Mental Irresponsibility.—In regard to the mental irresponsibility of women during the menstrual period, Krafft-Ebing reaches the following conclusions: 1. It is useful to consider the mental soundness of women during menstruation from a medico-legal point of view. 2. It is advisable, where a woman is held on a criminal charge, to ascertain whether the commission of the act coincided with the menstrual period; and by period is meant not only the days when there is actual flowing, but those before and after as well. 3. It is best to advise examination of the mental condition when such coincidence is established. This is indispensable when there is a personal history of neuropathic defect, of mental disturbance at the time of previous menstrual periods, or when the nature of the act reveals any striking features. 4. When the menstrual process exerts a powerful influence on the mental life of the subject, the accused should be given the benefit of extenuating circumstances in the infliction of the penalty, even although there be no proof of menstrual insanity. 5. When the offence or crime has, in a person whose mind is impaired, occurred during the menstrual period, she must be declared irresponsible, for there is every reason to believe the act due to emotional impulse. 6. But individuals, who by reason of menstrual insanity would benefit by acquittal on this ground, should be considered as dangerous in the extreme and subjected during the times of the menses to close surveillance. It is best to confine them in an asylum for the insane, where they will be comfortably cared for and often cured of this menstrual instability of mind.—*New York Medical Times.*

Etiology of So-called Continuous Fever.—According to Dr. Chassiotis, the two sources of infection which have been found to cause the phenomena of so-called continued fever—viz., typhoid and plasmodia of malaria—have not been found in some cases. Numerous observers have thought to explain the origin, in the absence of these, on various hypotheses, none of which are satisfactory. Chassiotis had the opportunity of examining and following many cases, clinically, and subsequently pathologically upon the autopsy table. Peyer's patches and the mesenteric glands were carefully examined for typhoid bacilli without success; likewise resulted the search for malaria plasmodia. Certain features of these cases were found to exist in common with those found in malaria, typhoid fever, scarlet fever, diphtheria, and other miasmatic affections. 1. In various organs, especially the spleen, liver, and kidneys, were found many embryonal or round cells. 2. A dilatation of the blood-vessels. Then many granules of pigment as in malaria, and due to destruction of red blood-cells. As regards the round cells three varieties were observed: 1. Large cells with an abundance of nuclear chromatin. 2. Smaller cells with an abundance of nuclear chromatin 3. Smaller cells with scanty nuclear chromatin. The examination of the blood revealed the most interesting features of Chassiotis's observations. He discovered numerous diplococci, of oval or rounded form and varying in size. In the beginning of the attack they are very small, but increase in size as the affection progresses, attaining a length of 0.16 μ to 2 μ. The forms are most perfect during the exacerbations of the fever; they show evidences of degeneration during the remissions of apyrexia. One of the most characteristic evidences of degeneration is the failure of the diplococci to stain well or uniformly. They are possessed of a slow motility in the blood plasma, when placed in a moist chamber. As they approach the edge of a red blood-cell, they show a tremulous motion. Within the white blood-cells one or more diplococci may be visible. They may lie at the periphery of the cells or completely fill them. If the temperature be very high and there is coincident weakness and emaciation preceding death, there will be marked poikilocytosis and diminution in the numbers of red blood-cells. In this condition each half of the diplococcus is semilunar in shape, with distinct space between the two, and appearance as though the whole were surrounded by a clear gelatinous caspule.—*Pacific Medical Journal.*

Fetid Endometritis of Old Women.—According to the Paris correspondent of *The Lancet* endometritis occurring in women after the establishment of the menopause is doubtless due in some instances to the reawakening of an old infectious process or to a necrobiosis accompanying the elimination of a moderate-sized fibroma: but these causes cannot explain other cases. Thus, Fritsch, and, later, Patru, ascribe its occurrence to a destruction of the endometrium. In some of these sufferers the symptoms recall those of cancer of the uterus—vaginal irritation, periodic flow of pus, emaciation, and straw-colored complexion. The importance of a correct diagnosis in such cases has impelled Dr. Maurange to publish three observations of the disease, for a description of which classical works on gynecology may be vainly thumbed. The first case was that of a woman, aged fifty-five, in whom menstruation had ceased at fifty. For the past few months she had lost flesh, the features were drawn, and the complexion yellowish. She complained of abdominal pains, with a constant discharge of a horribly fetid, thick liquid—so great was the stench that her *femme de chambre* could not bear to remain near her. An examination by Drs. Picqué and Josias, surgeon and physician respectively to the Paris Hospital, led to the diagnosis of cancer, despite the smallness and mobility of the uterus and the absence of lesions of the os. Hysterectomy was proposed and accepted, but fortunately for the patient the os was first dilated with laminaria, the removal of which gave exit to a flow of pus, floating in which were fragments of mucous membrane. Examination of one of the fragments failing to confirm the diagnosis of malignant disease, the uterus was thoroughly scraped, with the result that recovery ensued in a month. Two years later her appetite had returned, the complexion was normal, and all pains had ceased. The other two cases cited were similar to the first. It would appear that the disease occurs in women from five to fourteen years after the onset of the climacteric, that it attacks women who have had children as well as those who have never been pregnant, and that pathological antecedents have no appreciable influence on its occurrence. The symptoms are as detailed above, and, in addition, the sound enters for a distance of from seven to eight centimetres; its introduction is painful and its removal induces a copious flow of blood-stained pus whose fetidity surpasses even that of cancerous ichor. Only histological examination of *débris* collected by curettage can enable us to distinguish between this disease and cancer. In only one instance has this examination been made (by Dr. Maurange). The lesions discovered were those of chronic catarrhal endometritis—viz., glandular hypertrophy, leucocytal infiltration, and areolar hyperplasia. Microscopically the uterine mucous membrane is swollen, hardly ever ulcerated, and is easily detached with the curette. The prognosis is favorable if the following treatment be carried out: Dilatation of the os and thorough scraping of the uterine lining, followed by *tamponnement* of the uterine cavity with iodoform gauze.

Danger in Frozen Milk.—The *Lancet* is justly alarmed at the growing trade in frozen milk from Holland and Sweden, where there is no guarantee as to its freedom from contamination.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, July 20, 1895.

A STUDY OF TWINS.

THE subject of plural births in the human animal is one that has always attracted the attention of the curious, whether regarded from the anatomical or from the developmental point of view. A recent noteworthy contribution to the literature of twins is a comparison of the statistics furnished by the lying-in hospitals of the Scandinavian countries, and a study of a large number of personal observations, published by Dr. Drejer, in Christiania.[1] The author has had abundant opportunity, as physician to the large lying-in hospital of Christiania, for studying his subject, and although he presents little that is new yet his contribution is valuable, as is every study based upon facts.

Multiple births occur on the average in 1.17 per cent. of all cases, but this percentage varies within pretty wide limits in different races; among Europeans it appears to be highest in Slavonic peoples and lowest in the Latin races. The number of twin pregnancies is greater, both relatively and actually, among those living in the country than in city dwellers, and among the latter the proportion seems curiously to vary inversely as the size of the town.

There is a certain relation between human fecundity in general and the frequency of twin births, but there are also notable differences. Thus, a woman is at the period of maximum fecundity at the beginning of her sexual life, during the early years of her marriage, and while the husband is still young, but twin conceptions are more common in later sexual life, in women who have married late, and in cases in which the husband is considerably older than the wife.

The origin of the twins, whether from one ovum or two, was determined by Dr. Drejer from an examination of the membranes, a single placenta indicating a uni-ovular origin. In the cases studied by the author the ratio of uni-ovular to bi-ovular twins was as 1:3.7, a much larger proportion of uni-ovular twins than other investigators have found. In ninety-six cases, the placentas were weighed and were found to be as heavy relatively as in single pregnancies. The umbilical cord was, as a rule, shorter than in normal pregnancies, and its insertion was frequently marginal.

The diagnosis of twins is impossible before the end of the sixth month, and is at all times very difficult until labor has actually begun. In only 48.8 per cent. of twin pregnancies were the children carried to full term. The birth of the first child is apt to be tedious, owing to the fact that the uterus works at a disadvantage through the body of the other child, but the birth of the second child is easy and rapid because of the very effectual dilatation of the parts. The presentation in Dr. Drejer's cases was usually occipital, though less frequently so than in normal childbirth; breech presentations were common, especially of the second child. In one of the author's cases the placenta of the first child was expelled before the second child was born, but in all the other cases the two children were born first and then the placentas, these usually together. The question as to how long the accoucheur should wait after the birth of the first child before taking measures to hasten the expulsion of the second is one that has given rise to more or less discussion. In the Maternity at Christiania, Professor Schœnberg has established the rule to wait a full hour after the birth of the first child, and it is found that the accouchement is spontaneously completed within that period in eighty per cent. of the cases.

Among twins the number of boys is greater than that of girls, although the disproportion is not so great as in normal pregnancies; some observers have even asserted that girls are in excess. The two children are more apt both to be girls than to be of opposite sexes.

Of the twin births occurring in the author's practice, 13.22 per cent. of the children were still-born, and 11.98 of those born alive died within two weeks, a mortality much in excess of that following single births. The prognosis for the mother is somewhat less favorable than in uniparous accouchements—the increased mortality in the cases studied being due to the complications of pregnancy and child-birth, and especially to eclampsia. The danger of infection is perhaps a little greater than in the case of single birth, but in none of the author's cases did death occur from puerperal septicæmia.

ACROMEGALY AND GIGANTISM.

ABOUT a year ago an article appeared in the *Journal of Nervous and Mental Diseases*, by Dr. C. L. Dana, in which he described the brain of a person who was of gigantic stature, and who had acromegaly. The idea was suggested that gigantism was a disease allied to acromegaly, and that both were dependent upon disease or perverted functioning of the pituitary gland. A number of cases of giants with acromegaly were cited in evidence.

It seems that this theory was not propounded first by Dr. Dana, for in a recent article by Dr. Robert Massalongo, of the University of Padua, the claim is made that he published a theory of gigantism and acromegaly as long ago as 1892.

At the International Congress held in Rome last year, Professor Tamberini also published an article upon acromegaly, in which he asserted the same views, and cited a number of cases in which examination of the skeleton of giants showed that they were really cases of acromegaly.

Dr. Massalongo believes that the pituitary gland is

excessively active in its functioning in all cases of real gigantism; that after this condition has reached its climax, however, the gland begins to undergo retrograde changes, and coincidentally with this, the individual himself begins to show evidences of physical and mental decay. In the cases of acromegaly, he believes that the process is less complete, and that, in fact, acromegaly is only an abortive type of gigantism, both conditions being dependent upon this same underlying pathological change. A number of new giants are brought forward in support of this view.

Other authors, who take a more sceptical view regarding the importance of the pituitary gland in its relation to excessive growth, state that while it is true that the majority of giants are cases of acromegaly, yet this is due simply to the fact that gigantism furnishes a fruitful soil for the disease acromegaly to grow upon. In other words, giants are more disposed to acromegaly than ordinary individuals, hence the excessive proportion of such among them.

The subject is certainly an interesting one, although somewhat academic, so far as the ordinary practitioner of medicine is concerned.

OSTEOPATHY.

Life in the United States of America is made much more interesting, if not more safe, by reason of the various medical and surgical vagaries that crop out over the land. We venture to say that in no other country could such interesting phenomena as Christian science, "Perkinism," vegetarianism, Thompsonianism, mental healing, and a number of other interesting forms of pathological activity, develop. No sooner is one thoroughly exploited, than it begins to spread around the country; then, after a few years of picturesque and uneven existence, it dies out. Among the latest of the medico-surgical cults, is what is known in the West as "Osteopathy." It seems that at Kirksville, Mo., there is or was an institution known as the "Medical School of Osteopathy." This school turns out a class of practitioners who call themselves "osteopaths," and they have made themselves quite popular in certain sections of the great Southwest. The person who is at the bottom of "osteopathy," possesses not only skill in developing a medical art, but also in manipulating politicians. He succeeded in getting a bill through both houses of the Illinois Legislature, amending the Medical Practice Act of that State. The amendment was in the form of a law, which stated that nothing "in this Act shall be considered to prohibit services in a case of emergency, or the administration of family remedies, or the practice of osteopathy." The bill was vetoed by the governor, who gave the assurance, however, that any one confining his treatment to physical manipulation would not be prosecuted, thereby giving the "osteopaths" a quasi standing before the law.

We learn from the *Medical Fortnightly* that osteopathy has become so popular in Missouri as to call for scientific investigation of its merits, and Dr. Steele, of St. Louis, took the trouble to make such an investigation. He reports that the theory of the new school is this: There are two kinds of diseases, one coming from the displaced bones of the extremities, causing deformities, pain, etc.; the other from dislocation of some of the vertebræ, giving rise to diseases of the trunk. The same treatment, however, cures all cases, and this treatment consists in acts of manipulation, with perhaps an element of "suggestion." He says that the method certainly effects cures in cases of chronic rheumatism and sprains, in old dislocations, and in hysterical and neurasthenic pains. In other words, osteopathy is practically a form of massage.

BATHING AND DISEASE OF THE EAR.

Now that the summer season is at hand it may be well to remind our readers of some of the aural mishaps which occur to those who indulge in bathing, particularly in sea bathing, where there is a good deal of concussion from the surf. A correspondent of the *Lancet*, Dr. A. H. Cheatle, says that the common accidents to the ear are acute inflammation of the middle ear, diffuse inflammation of the external ear, the lighting up of an acute condition in a chronic suppurating otitis media, simple deafness due to swelling of a ceruminous plug. Besides this there are occasionally troubles from diving, such as concussion of the labyrinth and rupture of the membrana tympani. In order to avoid these accidents, Dr. Cheatle says that persons suffering from middle-ear discharge should never bathe at all, and that those who have had middle-ear discharge and whose membranes have healed should never bathe without some efficient means for preventing the water from entering the ears, such as firm plugs of cotton-wool with an oil-skin cap fitting tightly over them. Water remaining in a healthy ear should be let out as soon as possible. Acute otitis seems to be occasionally caused by water which has entered the naso-pharynx, hence the nose should be protected. Some advise that everyone who bathes should introduce a plug of cotton in the ear.

News of the Week.

The Medico-legal Society.—The Medico-legal Society of this city, which makes a specialty of holding congresses, has decided to hold another one in 1895. The meeting will be held in or near this city, September 4th, 5th, and 6th, and the science of medical jurisprudence will be discussed under nine different headings, ranging all the way from bacteriology to chemistry and crime.

The Case of Secretary Gresham.—In the *Journal of the American Medical Association* for June 26th, Dr. W. W. Johnston, of Washington, gives in great detail the clinical history of the last illness of the late Secretary of State. Mr. Gresham was taken ill April 30th, with an acute pleurisy with effusion. The disease ran about the ordinary course, and at the end of three weeks he was apparently convalescent. Suddenly, without much warning, an attack of pneumonia developed, from which the patient died on the third day.

The Secretary was evidently carefully watched and skilfully treated. We scarcely see the necessity, however, of publishing the minute details of such an illness, including the amount of buttermilk drank, the number of stools, etc.; but the record, as a whole, is an interesting account of the untimely and fatal illness of the lamented Secretary.

The Third International Congress of Physiologists will be held in Berne, Switzerland, on September 9 to 13, 1895, under the presidency of Professor Kronecker, Director of the Physiological Institute of the University of Berne. The official languages of the Congress will be French, German, and English. The cost of membership is ten francs. Titles of communications may be sent to Frederic S. Lee, Secretary of the American Physiological Society, Columbia College, New York City.

The Late Dr. John M. Byron.—At a meeting of the Medical Board of Columbus Hospital, held July 8, 1895, the following action was taken, relative to the death of Dr. John M. Byron, late Visiting Physician and Pathologist to the Hospital.

1. That we deeply regret the loss of Dr. John M. Byron, Visiting Physician and Pathologist to Columbus Hospital, and that we desire to place in the records of the hospital the following sentiments, as an expression of our regard for, and appreciation of, our late associate.

2. That in his death the science of bacteriology has lost a student whose intelligent devotion to investigation would have placed him among the most illustrious workers of that branch of medicine.

3. That his successful career, prematurely cut short by an infection derived, as he believed, from his daily laboratory work, has furnished another example of that true self-sacrifice, so characteristic of medical men in their devotion to duty.

4. That we deeply sympathize with his family in their bereavement, and it is hereby ordered that the foregoing record be transmitted to them, and sent to the local medical journals for publication.

STEPHEN SMITH, M.D.,
President of the Medical Board.
CHARLES H. LEWIS, M.D., *Secretary.*

Dr. F. T. Roberts has been appointed professor of medicine to succeed Dr. Charlton Bastian, at the University College, London.

Rabies in England.—Rabies is said to be increasing in England. In the first five months of the year 1892 there were only 11 cases reported. During the same period of the following year there were 37 cases, while in the first half of 1894 the number of cases reported was 80 ; and this year it is 373.

The Southern Medical Record has changed hands, and is now under the management of Dr. Bernard Wolf, of Atlanta, Ga.

The Medical Society of Virginia will meet in Wytheville, on September 3d. The President is Dr. Robert J. Preston, of Marion. The Virginia Society now numbers 860 members, and it is hoped that the coming meeting will result in increasing the membership to 1,000.

Laboratory Diphtheria.—Dr. Ruffer, the Director of the British Institute of Preventive Medicine, whose researches in regard to the antitoxin treatment of diphtheria are so well known, recently contracted a severe attack of the disease in the course of his investigations. Immediately on the nature of his complaint being ascertained he was treated by antitoxic serum, and, we are glad to learn, with most satisfactory results, as at last reports he was making very good progress toward recovery.

The Force of the Human Jaw.—Dr. J. V. Black, a dentist, of Jacksonville, Fla., has made some experiments as to the force exerted by the human jaw in chewing food. He says that the amount of pressure recorded in a single bite, varies from thirty to two hundred and seventy pounds. This maximum record, it is interesting to note, was made by a physician. The crushing force necessary to masticate ordinary beefsteak, Dr. Black says, is only forty to forty-five pounds, but the doctor has probably never lived in a boarding-house. He says that usually a good deal more force is applied than is necessary, viz., from sixty to eighty pounds, and he laments somewhat this waste of energy.

Ipecac in the Insomnia of Alcoholism.—Some years ago ipecac was greatly advocated as a hypnotic in insomnia due to alcoholism. Recently Dr. Waugh has discovered that twenty minims of the fluid extract of ipecac caused sleep in a patient when large doses of sulphonal had failed.

An Economist.—"If you insist on knowing the truth, madam," said the doctor, "your husband will not live twenty-four hours longer." "Good gracious!" ejaculated the broken-hearted but economical wife, "and yet you have sent in medicine enough for five days."—*Flieg. Blätter.*

Cholera is reported to be alarmingly prevalent in Prussian Silesia.

The Ontario Medical Council.—The Council of the College of Physicians and Surgeons of Ontario met on June 11th at the Council Building, Toronto, and was in session two weeks. The following-named members were elected officers for the current year: *President*, William T. Harris, M.D., Brantford ; *Vice-President*, A. F. Rogers, M.D., Ottawa ; *Registrar*, R. A. Pyne, M.D., Toronto ; *Treasurer*, W. T. Aikins, M.D., Toronto ; *Solicitor*, B. B. Osler, Q. C., Toronto.

The Hyams Case.—A great deal of professional interest has been aroused in Canada by what is known as the Hyams Case. According to the Canadian *Practitioner*, life insurance men, elevator experts, surgeons, and medical jurists have all taken part in it. A young man named Wells was found dead at the foot of an elevator shaft, and an examination apparently showed that the head alone had been injured. No special examination was made at the time the body was found, and two years passed before suspicions of foul play were strong enough to call for further investigation. The body was then exhumed and examined with as

much minuteness as possible under the circumstances. The head alone was damaged, but the injuries to it were of such a character as to completely destroy its continuity, for fractures were found involving, not only the vault, but the base, the face, and even the lower jaw. The photographs published by the *Practitioner* showed that the skull was apparently almost comminuted by the force of the blow or fall, or both. The ground taken by the prosecution was that more than one blow was necessary to cause all the injuries found. A large number of experts were summoned on each side, and the case was brought, according to our contemporary, to "an unsatisfactory termination," but what that termination is we are not informed. The weight of the medical evidence seems to have been that more than one blow was necessary in order to produce the effects upon the skull.

The Absorption of Salicylic Acid.—Drs. Lenoissier and Lanois have made some experiments upon the method of absorption of salicylic acid. They found that the application of salicylic acid in solution upon the skin led to its absorption in small amount. They made some experiments upon the method by which this was absorbed. When dissolved in alcohol, and placed upon the arm and then covered with a bandage, it was found that the acid was not absorbed if the skin was kept cool. If, on the other hand, it was kept warm by external applications, salicylic acid was soon found in the urine. They concluded, therefore, that the salicylic acid is volatilized and absorbed in that way. The fact that this drug has a considerable efficacy when applied externally in rheumatism is well known, and the explanation of the method of absorption seems to be satisfactorily determined.

New York and Paris Saloons.—While New York is trying to get its saloons open, Paris is trying to get some of hers shut. New York has about 9,000 saloons. Paris had, in 1890, 29,583 wine-shops. Eminent physicians, such as Laquean and Lancereaux, consider that the abuse of alcohol is increasing the amount of phthisis in Paris. In 1893 there were 10,681 deaths from this disease, about two-thirds being in men. In New York the total deaths from this disease were, in 1893, only 2,128. It is evident that phthisis, like the wine-shops, is two or three times more prevalent in Paris.

Shall Insane Criminals be Imprisoned or Put to Death?—In the communication with this title appearing in the issue of July 13th, the address of the author, Dr. J. B. Ransom, should be Dannemora instead of Clinton. On pages 40 and 41, where figure 6 is mentioned in the text, it should read figure 13, and figure 7 should read figure 12.

Imprisonment of a Physician for Negligent Prescription.—A young physician in Berlin has been recently condemned to a month's imprisonment for homicide through negligence (fahrlässiger Tödlung). He had a woman under treatment suffering from obstinate trigeminus neuralgia. She came to him on May 22d to ask for a prescription for a narcotic, as she had suffered from sleeplessness for a long time. Knowing that she did not react well to narcotics, he prescribed 6 grammes (1½ drachm) of chloral hydrate. He signed the prescription: "To be taken in two portions before going to bed." The apothecary also wrote the same directions. The woman told her friends that according to the doctor's orders she was to take half before going to bed, and the remainder after getting into bed. After taking the first half she seemed drunk, she became lively, laughed, and gesticulated; she then received the second half and never woke again. The autopsy resulted in the verdict of death by intoxication with chloral hydrate. The chemical investigation showed that not more than six grammes had been taken. The Pharmacopœia prescribes three grammes as the maximum dose. The prescription, however, ordered six grammes, to be taken in two portions, the one shortly after the other. The accused stated that he had repeatedly impressed on the patient that she should take half at once, and if she did not then sleep she should take a teaspoonful more after an interval of five hours; the remainder she should take the following morning. The statements of all the friends of the deceased were opposed to this, however. The court, after the interrogation of two experts, awarded a month's imprisonment, as it held it to be proved that the fatal result was solely attributable to the ambiguous directions, and that the physician, in exceeding the maximum dose, was in duty bound to exercise the greater caution.—*Medical Press.*

Piano Playing and Neuroses.—A corresponding member of the Paris Academy of Medicine has sent to that learned body a memoir in which he maintains that the numerous cases of chlorosis, neuroses, and neurasthenia observed among young girls is due to learning to play on the piano and the hours devoted to practising. He has drawn up careful statistics from which he concludes that, among six thousand pupils obliged before attaining the age of twelve to learn to play the piano, nearly twelve per cent. suffer from nervous troubles. The author does not attempt to draw up statistics of the victims among persons who have to listen to their performances.—*British Medical Journal.*

Dr. George F. Shrady has been appointed attending surgeon to Columbus Hospital.

Obituary Notes.—Dr. C. M. Fields, died on July 12th at Plainfield, N. J., from an overdose of morphine and cocaine. He was found in his apartments in an unconscious condition. He was compelled to cease practice several years ago, and since that time he has travelled extensively in foreign countries. He was born in Bound Brook, and was forty-five years old.—Dr. Judson C. Nelson, of Truxton, Cortland County, N. Y., died July 11th, of angina pectoris, in his seventy-second year. He was a graduate of Geneva College in 1848, and began practice at once in Truxton. He went out as surgeon of the Seventy-sixth New York Volunteers. After the war he returned to Truxton, where he had an extensive practice, both family and consultation. He was a gentleman of fine appearance, although his health had been much impaired by his army life. He was a Democrat and served two terms in the Assembly. He had also filled other offices in the county. He leaves a wife, a son, and a married daughter.

Reviews and Notices.

Ectopic Pregnancy: Its Etiology, Classification, Embryology, Diagnosis, and Treatment. By J. Clarence Webster, B.A., M.D., F.R.C.P. Ed., Assistant to the Professor of Midwifery and Diseases of Women and Children in the University of Edinburgh. With Eighty Illustrations of Naked Eye and Microscopic Appearances. Pp. 240. New York: Macmillan & Co. 1895.

The work is most comprehensive, scientific, and scholarly. It will prove a great acquisition to the knowledge of the profession on this much-disputed subject. The points which render it of special value are its intelligent review of the previous literature, a broad discussion of the theories as to the causation of ectopic pregnancy, and an exposition of existing conditions, which have a greater value than any hitherto advanced, owing to the fact that it is supported by the evidence given by frozen sections prepared by Dr. Berry Hart and the author. These, with the careful microscopic studies, give a practical value to the work which cannot fail to make it appreciated.

In his chapter on treatment he says that the tendency of the present time is toward the non-employment of electricity. He doubts that without puncture of the sac sufficiently strong currents can be employed to prove efficacious. He favors abdominal incision rather than the vaginal methods of reaching the tumor in surgical procedure.

Medical Gynecology. A Treatise on the Diseases of Women from the Stand-point of a Physician. By Alexander J. C. Skene, M.D., Professor in the Long Island College, Brooklyn, formerly Professor in the New York Post-Graduate Medical School, etc. With Illustrations. Pp. 529. New York: D. Appleton & Co. 1895.

Dr. Skene writes this book to advocate conservative measures in gynecology, and to accentuate the importance of medical treatment, and its success, rather than the surgical and radical measures, to which gynecologists are tempted to resort in their haste to obtain speedy and brilliant results. The intention is a laudable one, and the long experience of Dr. Skene in the practice of the diseases of women has not failed to yield results that are of use and profit to the profession, as embodied in this work. In his discussion of the general conditions of woman in her mental and physical education, her heredity and environment, it is evident that the writer is not thoroughly acquainted with "the new woman." The reader will find of especial value his chapters on pelvic inflammations and the diseases of the urinary organs. His wide experience in Kings County Insane Asylum is the basis upon which he gives the result of his experience. He agrees with the few gynecologists that have had to do with these unfortunate women, that systematic gynecological treatment is impossible for them, and that the only results are those which can be obtained from treatment given under the influence of an anæsthetic. He finds nitrous oxide gas the most useful and easily administered anæsthetic for this purpose.

The Evolution of the Diseases of Women. By W. Balls-Headley, M.A., M.D., F.R.C.P. Pp. 375. London: Smith, Elder & Co. 1894.

The author, who is the Lecturer on Obstetrics and Diseases of Women at the University of Melbourne, gives us the rather unusual view of gynecology, that of the Australian. The writer is determined to make good the promise of his title, and one could almost believe that he had taken the word evolution and its adjective evolutionary as a trade-mark, by which all his chapters were to be known. His definition of subinvolution illustrates what is meant. "Subinvolution," he says, "is an evolutionary state in which the various structures hypertrophied by pregnancy and stretched by parturition have failed to return to their normal retracted state," etc. Under the discussion of every disease there is a paragraph entitled "Progressive Evolutionary Disease." This continual reiteration is not always *apropos*, and mars the effect of the work. He has given introductory chapters on sexual relations and modern marriages, lamenting the lateness of marriages, and the decrease of offspring. He exaggerates, judging from an American stand-point, the difficulties of childbirth, when he says, "One out of nine in hospitals and a larger percentage among the upper classes cannot produce her child without the aid of forceps, and many more not without lacerations, misplacements, and evolving disease." In inflammatory diseases of the uterus and displacements in virgins he gives great prominence as an etiological factor to unsatisfied sexual desire. Instead of being a usual cause, it is very rare, judging from American stand-point and observation.

The book is written clearly, concisely, and comprehensively. The chapters on the various diseases present clear pictures to the student. The illustrations are most excellent, from their simplicity and the clearness with which they demonstrate the points which are to be shown. The chapter on treatment is much too general to be of very much use, though it enforces several salient points, such as dilatation, drainage, and curettement, which one little accustomed to gynecology might in his attention to applications to medicines not yield the considerations due.

Diseases of the Ear. A Text-book for Practitioners and Students of Medicine. Pp. 645. By Edward Bradford Dench, Ph.B., M.D. New York: D. Appleton & Co. 1894.

The author is to be commended for the great amount of labor performed in the compilation of this book. It contains the matter usually embraced in works on the ear; 170 pages are thus devoted to the anatomy, physiology, and examination of the organ, and 464 pages to its diseases and their treatment. That most important feature of aural surgery, namely, the surgery of the conducting apparatus, is considered pretty fully in 50 pages. It would have been a courteous attention to the authors' colleagues in this country, whose successful labors in this field opened to him the way for such work, had he made some acknowledgment of his indebtedness to their efforts. The attempt so extensively to illustrate operations on the middle ear by means of pictures never has been attempted before, so far as we remember at least, in any work on the ear, and if one may venture to predict from the impression these produce on the mind, the effort will not be repeated. Nor are the lithographic views of the drum-head, as shown in Plates V. and VI., and intended to represent various diseased conditions of the membrane, of any greater value. The publishers seem to have spared no expense in illustrating the book, and some of the illustrations are useful, but we can see no advantage to be gained by inserting in a modern work on the ear pictures of the valueless catheters of Pomeroy and Noyes.

Practitioners and students of medicine are in need of a precise and practical work on the ear, but this big book is too verbose with theoretical and obsolete matter, which has been accepted by the author in lieu of personal knowledge, to meet this want.

Immunity. Protective Inoculations in Infectious Diseases and Serum-therapy. By George M. Sternberg, M.D., LL.D., Surgeon-General United States Army; Ex-President American Public Health Association; Honorary Member of the Epidermological Society of London, of the Royal Academy of Medicine of Rome, of the Academy of Medicine of Rio Janeiro, of the Société Française d'Hygiene, etc. New York: William Wood & Co. 1895.

The author divides his monograph into two parts, the first dealing with immunity, natural and acquired, in animals and man, the second treating of protective innoculation and serum-therapy. He takes the ground that pathogenic bacteria are common to the human economy during health, but are kept in abeyance by the *vis medicatrix naturel*—in other words, that blood-serum is an antitoxin. As early as 1881, three years prior to Metschnikoff, Dr. Sternberg affirms that he was the first to claim that leucocytes were bactericidal, that immunity is acquired through acclimation, inoculation by attenuated viruses, and an attack of any one of the specific diseases. In part second a chapter is devoted to an elaborate and practically interesting consideration of each of the infectious diseases as occurring in animal and man. An elaborate bibliography is annexed. In the chapter on pneumonia the author claims priority over Fraenkel in the discovery of the "micrococcus pneumoniæ crouposæ." To the general practitioner this work is of inestimable value, inasmuch as it treats in a thoroughly scientific manner all the important questions bearing upon the subject of serum-therapy. It gives a description of the latest methods employed in the pursuit of this very interesting and promising study. The facts presented are founded on a long series of experiments and studies by the author, extending over a number of years under most favorable circumstances and with unusual facilities. To anyone who studies this book carefully it will appear self-evident that serum-therapy has opened up a large and useful field to the student of therapeusis. Cer-

tainly no one has a better right than the author to say thus much from the stand-point of an acknowledged authority on the subject of which his admirable work so interestingly and instructively treats.

GOUT AND ITS CURE. By J. COMPTON BURNETT, M.D. Philadelphia: Boericke & Tafel. 1895.

THIS is a well-written and readable little treatise on the therapeutic management of gout from the stand-point of a homœopathic practitioner, for whom urtica urens takes the place of the orthodox colchicum. The author is an ardent disciple of Hahnemann, but his book is none the less interesting, and it contains numerous little hints that may profitably be followed even by those who have no faith in the mother tincture of nettle. It is even possible that urtica urens will do as much for gout as colchicum—which is not very high praise for either remedy.

MANUEL DE DIAGNOSTIC CHIRURGICAL. Par SIMON DUPLAY, Professeur de Clinique Chirurgicale à la Faculté de Médecine de Paris. E. ROCHARD, Chirurgien des Hôpitaux, et A. DEMOULIN, Chef de Clinique Chirurgicale de la Faculté. Premier Fascicule. Paris: Octave Doin. 1895.

THIS manual of surgical diagnosis is a *résumé* of the course of instruction given by Professor Duplay and his assistants at the School of Medicine in Paris. This first volume contains general directions on the examination of the patient and the methods of clinical exploration, and the diagnosis of diseases of the head, face, neck, and spinal column. It is a very practical little work which cannot but be of assistance to any student or young practitioner of surgery. A few well-executed illustrations, printed when necessary in colors, add to the usefulness of the manual. The concluding volume is promised for the end of this year.

THE YEAR-BOOK OF TREATMENT FOR 1895. A Critical Review for Practitioners of Medicine and Surgery. Philadelphia: Lea Brothers & Co. 1895.

THIS excellent annual has become such a standard work and such a favorite that there is little to say each year but to repeat the praise of the year before. The present volume is fully up to the standard of its predecessors, and with it in his library the physician would have no excuse for not keeping abreast of the times in the therapeutic art.

FIFTEENTH REPORT OF THE STATE BOARD OF HEALTH OF WISCONSIN. 1893–1894. Madison: 1895.

THIS volume contains the usual matter contained in reports of boards of health, but possesses an added interest because of the small-pox which the board had to fight in the city of Milwaukee, and of the rioting excited by its efforts to isolate the patients. The incident is well described in the report.

ANNUAL REPORTS OF THE MANAGERS AND OFFICERS OF THE STATE HOSPITALS OF NEW JERSEY FOR THE YEAR ENDING OCTOBER 31, 1894. Trenton: 1894.

THIS volume contains reports of the hospitals at Trenton and Morris Plains. Several interesting cases are related in the report of Dr. Evans, the Medical Director of the Morris Plains Hospital.

TRANSACTIONS OF THE SIXTEENTH ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL SOCIETY, Held in the City of Washington, D. C., May 30, 31, and June 1, 1894. New York: D. Appleton & Company. 1895.

THE meeting of the American Laryngological Society in Washington a year ago must have been one of more than average interest, if we can judge from the contents of the volume before us.

TRATTATO DE PATOLOGIA E TERAPIA CHIRURGICA GENERALE E SPECIALE. Dal Professore FRANCESCO DURANTE, Direttore della Clinica Chirurgica della R. Università di Roma. Vol. I. Parts I. and II., Roma: Società Editrice Dante Alighieri. 1895.

THIS work, written by the foremost Italian surgeon, Professor Durante, of Rome, promises to be a most valuable addition to surgical literature. The present fascicule contain seven chapters—on inflammation and its results, surgical fevers, traumatisms, the healing of wounds, the complications of wounds, and tumors. The author treats these general subjects in a way to hold the interest of the reader while at the same time instructing him, and in this his work is facilitated in no small measure by some seventy well-made illustrations.

PATHOLOGY AND TREATMENT OF DISEASES OF THE SKIN, FOR PRACTITIONERS AND STUDENTS. By MORIZ KAPOSI, Professor of Dermatology and Syphilis, and Chief of the Clinic and Division for Skin Diseases in the Vienna University. With Eighty-four Illustrations. Translation of the last German Edition under the Supervision of James C. Johnston, M.D. New York: William Wood & Co. 1895.

FORTUNATELY we are not called upon to speak of another text-book to be added to the rather formidable list of those devoted to skin diseases which have appeared within a comparatively brief period. It is in this instance a translation which claims attention. Kaposi's work is well worthy of reproduction for the benefit of those whose knowledge of German does not permit the full enjoyment of the original text. The reproduction as it comes to us shows unmistakable evidence of having been worthily done.

Not every student has the advantage of a course of study in Vienna, and the great majority of practitioners are debarred from even reading the works of distinguished foreign teachers in the original. We therefore welcome such a publication, which affords the English-speaking physician an opportunity to become familiar with the prevailing views and practices of the Vienna school of dermatology. In the preface to this American edition, written by George Henry Fox, a just tribute is paid to the author's attainments and ability.

An occasional word or turning of a sentence may remind one that the text was originally German, but as a whole the translation shows great care and accuracy, while at the same time the English has been made as fluent as a strict following of the text would permit. On page 336 the omission of a period in the formula for Unna's ointment might cause one to read ten grammes of corrosive sublimate where one gramme is the quantity intended, but as the author states that he has never seen any benefit from this application in lichen planus, perhaps it would not be considered a serious error.

We may note in passing that the author still maintains the identity of Besnier's pityriasis rubra pilaris with his lichen ruber acuminatus; that he admits the adjective "contagiosum," as justified in the designation of the epithelial molluscum, while leaving it as an open question whether the gregarinæ are the carriers of infection. "Alopecia areata," he says, "we are forced to assume, is due to trophic disturbance of entirely unknown origin." The many experimental investigations of recent times and the changes of views based upon new discoveries have not operated to cause as great alterations in the text of this last edition as one might be led to expect. Still, enough will be found to interest those most familiar with earlier editions. There is one full-page colored plate, but this, as well as the other eighty odd illustrations, is of histological subjects. The impression is made of a serious, conscientious work upon which student and practitioner can alike rely.

Salicylic Acid Externally in Rheumatism.—Dr. Kinnicutt reported at a meeting of the Practitioners' Society upon the use of salicylic acid by inunction in cases of acute articular rheumatism. The formula used by him was that of Bourget, viz., salicylic acid ten parts, lanolin ten parts, lard one hundred parts. Two drachms of the pomade were rubbed into several areas on the trunk and extremities, every four hours, the total daily inunctions representing sixty grains of salicylic acid. The absorption was very rapid, requiring no more than ten minutes for the single inunction, and it was unattended with any irritation of the skin. No covering was employed. The inunction of two drachms of the pomade, representing ten grains of the acid, permitted the discovery of the latter in the urine, at the end of four hours. It had proved to be an efficient method of introducing salicylic acid into the economy, and of the treatment of acute articular rheumatism. It possessed the advantage of not producing disturbances of digestion.

The Plague has made its appearance in Foo Chow, China. There is no pretence of sanitation in that city, so the epidemic will probably continue until the soil has been exhausted.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Seventeenth Annual Congress, Held at Rochester, N. Y., June 17, 18, and 19, 1895.

FIRST DAY—MONDAY—JUNE 17, 1895.

President's Address.—The President, DR. JOHN O. ROE, of Rochester, delivered the opening address welcoming the members of the Association to the Flower City. He believed that these annual meetings were productive not only of scientific, but also of social good. Old friendships were cemented and new ones formed. In the friendly intercourse of such gatherings, much could be learned which could not be incorporated into formal papers.

Regarding the laryngological progress of recent months, he would call attention especially to the value of antitoxin in diphtheria, and to the great progress made in the treatment of tubercular disease of the upper air-passages, by Krause, Heryng, and their followers.

The President then read a paper on "The Relation of Damp Air to Diseases of the Upper Air-passages with Especial Reference to the Lake Region."

No one region is good climatically for all diseases, nor can it promote the vitality of all the bodily organs. Conditions good for respiratory difficulties are apt to prove the opposite for biliary troubles, and vice versa. This may result from either the effect of the atmosphere on the organs directly, or from its effects on the habits of the individual.

The climate of the Lake region seems to exert an injurious effect on the nose, throat, and lungs, whereas in this locality biliary disorders are not common. It is humid and characterized by sudden variations of temperature, with a low mean annual temperature. Any climate depends partly on the nature and degree of cultivation of the soil, on the elevation of temperature, and the position of a given locality with reference to the sea-level. In the Lake region, the soil is in places light and sandy, and in other places heavy and underlaid with clay. This sub-soil condition largely determines the amount of moisture in the atmosphere. Hence the importance of thorough drainage to render any given locality healthy. The sandy soil is naturally drained, so to speak, but the heavy soil requires the aid of sanitary science. The Lake region is highly cultivated and this also tends to lessen the amount of atmospheric watery vapor, and the activity of the circulation varies according to the latter.

The chain of great lakes sends down over the region under consideration large volumes of cold air, and there are consequently frequent and rapid changes of temperature. Early warm days of spring are succeeded by chilling blasts from the north. The amount of cloudiness is considerable, averaging six and one-tenth days out of ten, according to the records of the past twenty-five years. There is an average rainfall of 27.8 inches.

The damp-air currents check the insensible perspiration and thus affect the body unfavorably. The mucous membranes, and especially the nasal mucosa, bear the brunt of this onslaught. Endosmosis and the alterated elimination both lead to turgescence, hyperæmia, and hypernutrition, and from the naturally abundant blood-supply of the nose, this organ is especially exposed to deleterious influences.

A pernicious American habit is that of sleeping with open windows. A temperature is withstood during the night, when bodily resistance is low, which could not possibly be borne with comfort during the day. Hence the frequent colds referred to exposure the day before, but which are in reality due to night air, and thus naso-pharyngeal catarrh has come to be known as the "American" disease.

The relation of damp air to phthisis was pointed out by Bowditch over thirty years ago, and though we then knew nothing about the tubercle bacillus, the correctness of his views is now generally admitted; for the damp air and damp soils undoubtedly prepare the tissues for bacillary invasion. We should most carefully drain our lands and houses, and thoroughly ventilate our rooms, as prophylactic measures.

Desiccated Thyroids in Goitre.—DR. E. FLETCHER INGALS, of Chicago, read a paper with this title. During the last fifteen years he has treated eighty-seven cases of bronchocele and exophthalmic goitre. Formerly he gave potass. iodid., grs. v.–x., thrice daily. If the patients were not distinctly improved in two or three weeks, he gave iodine tincture, gtts. v.–xv., three or four times daily, administered in capsule and followed by a large goblet of water, beginning with the minimum dose and increasing one drop daily; or he would inject a three to five per cent. solution of carbolic acid in water and glycerine—using from twenty to fifty minims at one injection, and injecting once a week.

During the past three or four years he has used thyroid preparations of various kinds, and in his last six cases desiccated thyroids. Six grains of this preparation represent one entire gland. Dr. Ingals then gave outline clinical histories of his last six cases. All, with one exception, are still under treatment. Several of them had previously been subjected to the old style of treatment. He had obtained reports from other physicians who had used the desiccated thyroids, and was able to report on 50 cases in all. Taylor's series of 25 cases showed improvement in all but 7. The neck was uniformly diminished in size. As unpleasant features of the treatment, headache was reported in thirty per cent., dizziness in thirty-seven per cent., and increased rapidity of pulse in twenty-five per cent. Out of the 50 cases the size of the neck was reduced in 38. In addition to the foregoing unpleasant symptoms, were to be noted trembling, weakness, backache, nausea, loss of weight, and in one case uterine contractions which could be directly traced to the effects of the remedy. He would, from his study of the question, draw the following conclusions: 1. Thyroid products exert a powerful effect on the nervous and circulatory apparatus, as evidenced by head pains, rapid pulse, and fluctuations in weight. 2. These symptoms may arise from a daily dosage of from one and a half to two thyroids. 3. From cases observed it is not irrational to suppose that incautious dosage might produce fatal results. 4. The desiccated preparations are the preferable mode of administration. 5. Internal administration offers as good results as hypodermatic use. 6. The dosage should commence with two grains thrice daily, and run up to four or eight if necessary. 7. The effects are not constant in different patients, nor are they the same at all times in the same individual. Some of these may be due to incidental digestive disorders. 8. The remedy is of value in myxœdema. 9. In exophthalmic goitre, the gland is reduced in size, but in enlargement (not of the exopthalmic type), rapidity of cardiac action may be aggravated, instead of benefited. 10. Cystic glands do not seem to be benefited. 11. There is no evidence that thyroid therapy has any place in diseases other than the foregoing.

The discussion was opened by DR. E. L. SHURLY, of Detroit. He had used the ordinary extract of thyroid in some twenty cases, with disappointing results. He related the case of a boy from whose neck the entire gland had been removed some years ago, with the result that it seemed to diminish the boy's physical growth, and three or four years later he had developed a mental apathy and a peculiar piping voice. The movement of the cords and arytenoids appeared normal, except that the normal phonatory tension of

the former was markedly deficient. For the past two years the boy had been on thyroid extract (previous subdermic administration having proved useless), with the result that the tension of the cords was much better. He thought that laryngologists should protest against the whole removal of the gland for any purpose whatever. Experiments have shown that the retention of a very small portion will prevent the untoward results which follow its entire extirpation.

Dr. W. E. Casselberry, of Chicago, had used the remedy in one case of exophthalmic goitre, giving a preparation of fresh gland twice a week. His patient was improved, but not well. He called attention to a recent article by Paul Bruns, of Tubingen, who had shown from a series of cases that the younger the patient was, the more likely was he to be benefited. Thus all his cases in the first decade of life were cured; of those in the second decade seventy-five per cent. recovered; then the recoveries rapidly diminished as the age increased, and of the cases over forty years, scarcely any got well. Béchère had produced a fatal result in a monkey in ten days under thyroid feeding, sudden death resulting from heart failure.

Dr. Ingals, in closing the discussion, stated that in view of the possible causative agency of infected water in causing goitre in certain districts, all patients should be made to drink distilled or otherwise purified water.

Electrolysis by a Current Controller for the Reduction of Spurs of the Nasal Septum.—This was the title of the next paper, read by Dr. W. E. Casselberry, of Chicago. Electrolysis is not a universal substitute for other procedures, as it has well-defined limitations. A review of the literature shows that extravagant claims have been made for it, some of which are illogical in argument and unsupported in clinical experience. Dr. Casselberry then described a McIntosh current controller which he uses in connection with the Edison current. The ideal electrolytic current is one of moderately high tension (voltage) and of comparatively low current strength (ampèrage). He follows the so-called bi-polar method and uses needles of irido-platinum.

The histories of ten cases were next given. These can be divided into three types:

1. Spurs strictly cartilaginous. Here electrolysis will remove the offending mass, but one must be careful not to carry the process too far, else perforation may result. From 15 to 40 milliampères, and séances of from six to eight minutes are sufficient to dentalize cartilage.

2. Spurs partly bony and partly cartilaginous. Here electrolysis is beneficial directly proportional to the cartilaginous percentage of the mass to be removed. Only the cartilage disappears; the bone does not.

3. Spurs wholly of bone. Here electrolysis is useless.

The author concluded as follows:

1. Spurs of the first type can be removed by electrolysis. There is no danger of hemorrhage, but even here it is not a universal substitute for surgical treatment.

2. Spurs of the second type are removable only in part.

3. Spurs of the third type cannot be removed, as no needles will penetrate the bone.

4. Deviations cannot be remedied by this method.

Dr. J. E. Newcomb, of New York, opened the discussion, narrating his own experiences with this method, and taking strong issue with the continental authorities who claimed that it was useful in bony spurs or deflections of the septum.

Dr. W. H. Daly, of Pittsburg, would condemn the method as antiquated, as a waste of time, and as involving the use of that most unreliable of all apparatus—an ampère meter. What we really did was to cauterize, rather than to electrolyze. He preferred the usual surgical procedures, particularly the trephine driven by the De Vilbiss motor. Moreover, Dr. Casselberry's current controller could not be used with alternating currents.

Dr. E. P. Shurly thought that to use electrolysis for these spurs was analogous to trying to amputate a thigh by lunar caustic.

Dr. Jonathan Wright, of Brooklyn, thought there was a legitimate field for electrolysis in cases of phthisis and other debilitated states, where we did not wish to risk hemorrhage and shock. These patients were in a delicate position and it was easy to send them down hill.

Dr. Ingals said it was possible to remove soft anterior spurs with the fine cautery tip heated to whiteness.

Dr. John H. Loumar, of Cleveland, believed that the most reliable continental authorities were against electrolysis.

Dr. S. Hartwell Chapman, of New Haven, thought Dr. Casselberry's apparatus faulty in that it did not sufficiently reduce the initial current strength.

Dr. A. B. Thrasher, of Cincinnati, inquired whether the bipolar method was less painful than the monopolar.

Dr. Casselberry replied that it was. He admitted the validity of Dr. Chapman's objection to his apparatus, and hoped to remedy it in the future.

Is Acute Tonsillitis in any Way Dependent on the Rheumatic State?—Paper by Dr. George B. Hope, of New York. (Read by Letter.) He believes that the very generally accepted theory of tonsillitis attributing it to an underlying rheumatic or gouty diathesis, is not substantiated by the results of clinical experience, and considers the theory as largely the result of the natural disposition to fall into line with time-honored statements which continue to pass current and are not subjected to careful analysis.

The point is taken, that patients subject to tonsillitis do not commonly afford a history of rheumatism, either proximate or remote, and that, on the other hand, rheumatic individuals rarely suffer from tonsillar inflammations. It is a striking fact that the tonsil is, in later life, less and less disposed to acute attacks, while rheumatic tendencies become more and more manifest with advancing years. On pathological grounds, rheumatism should attack a sero-fibrous rather than a muco-fibrous or lymphatic structure such as the tonsil. Carrying the argument still further, it is claimed that peri-tonsillar suppuration is clearly of an infectious nature, and is frequently a sequel of intra-nasal operations.

The conclusion deduced from the foregoing propositions, is that the favorite anti-rheumatic treatment, as guaiac or the salicylates, addressed to the causation is either erroneous in practice or acts independently and by a method not clearly understood. Such remedies are not to be regarded as scientific, and must be adjusted to the varying conditions of each individual case. Moreover it is not proven that they either abort or mitigate the cause of the disease. After the reading of papers, there was the following presentation, of apparatus and instruments: Dr. J. W. Gleitsmann, of New York, a nasal conchotome. Dr. J. W. Farlow, of Boston—picture of Ferdinand I. of Germany, who died in 1524, and is supposed from the peculiar physiognomy to have had adenoids in the naso-pharyngeal vault. Dr. Morris J. Asch, of New York, a modification of Gradle's post-nasal forceps, also Bors's dilating intubation apparatus for laryngeal stenosis, and a mouth gag. Dr. A. Coolidge, Jr., of Boston, a cartilage knife and a dilator for syphilitic adhesions of the soft palate to the post-pharyngeal wall. Dr. J. C. Mulhall, of St. Louis, a current controller for applying the alternating current to the conditions of galvano-cautery work.

Second Day, Tuesday, June 18, 1895.

Lipomata of the Larynx.—Dr. J. W. Farlow, of Boston, related the clinical histories of two cases of lipoma and showed specimens and illustrative diagrams. The first one was a growth of the inside of the right cheek occurring in a boy two years old. It appeared

of a reddish lobulated appearance, was soft, smooth, and not ulcerated, looking in fact like a portion of the parotid and attached just anterior to the mouth of Steno's duct. Removal with cold wire snare, no hemorrhage. The lipoma of the larynx occurred in a male, aged sixty-six, in good health till fifteen years previous, when he noticed a growth coming from somewhere in the throat and projecting out between the teeth. A piece two inches long was removed by scissors. In March, 1893, it had again grown and was so long that the patient had to hold a small piece of cloth about it to keep it from getting between the teeth. It seemed to run down into the larynx and to cause suffocative attacks, from getting nipped between the cords and running down into the trachea. A cold wire snare and long curved scissors removed another piece. Patient was then lost sight of, but again returned with a recurrence of the growth and the old symptoms. The entire mass was then removed with the galvano-cautery snare, and its attachment found to be above the right arytenoid. Report of pathologist, "sub-mucous lipoma." No recurrence in three months.

Some Remarks on Removal of the Tonsils.—This was the title of Dr. Farlow's second paper. He discussed the question solely from the point of the choice of the method of operating. He first breaks up adhesions between the tonsils and the faucial pillars. If adenoids are to be removed at the same time, he anæsthetizes the patient and first removes the faucial tonsils by a special variety of wire écraseur, which he exhibited, and then removes the adenoids. This answers well for large tonsils in large mouths, but the condition is frequently seen in children with small mouths and narrow jaws. The tonsil is the more easily encircled by the wire loop (No. 5 or 7 steel piano wire), by being pressed in from the outside. This method is also applicable in adults, and the speed of tightening the loop depends on the consistency of the tissue to be removed. Ice can be used after operation, and cocaine applications before sections of the tissue removed have shown that everything has been taken out even down to the sheath of the tonsil.

Dr. Farlow also showed the tonsil punch of Ruault, of Paris, and the conchotome of Hartmann, both of which had been of service in removing the tonsil piecemeal. There was no hemorrhage to speak of with any of the foregoing instruments. The punches were useful for the removal of the tonsillar masses high up between the pillars, and knives suitably shaped could be used to open up fragments of tissue to be removed by the punch. He had tried galvano-cautery, but had found it very tedious.

Dr. F. H. Bosworth, of New York, said that if we cut into any lymphoid tissue, bleeding was possible, but it was rare in children. The large adherent masses between the faucial pillars must be dug out in some way, but the large projecting tonsils could be guillotined. No one instrument would answer for every case.

Dr. Ingals had found bleeding more common in children whose tonsils were not large at the time of operation, but in whom removal seemed indicated. Cocaine did not anæsthetize, and it promoted bleeding.

Dr. Carl Seiler, of Philadelphia, thought that the Matthieu fork instrument was faulty as generally constructed, in that the long diameter of the fenestrum was vertical instead of horizontal as it should be.

Dr. Daly thought that more bad surgery had been done on the tonsils than on any other part of the body. Mackenzie's instrument doesn't but half finish the task; we must trim with knife or forceps. He had had four or five alarming hemorrhages.

Dr. Casselberry would assert most emphatically that children, as well as adults, may bleed, and he never operated without having the galvano-cautery close at hand. In fibrous tonsils he preferred the hot snare. It was difficult to separate adhesions, but if he could get the muscular pillars free he did not hesitate to sacrifice a little mucous membrane if necessary.

Dr. Shurly had had two hemorrhages in children. We must estimate the nature of the tonsil and the amount to be removed, and must be prepared for an abnormal distribution of vessels. In igni-puncture he does not insert the cautery tip in the crypts, but diagonally between them. He aims to cut across the lymph-spaces and set up a new inflammation in place of the old chronic proliferating process. He would differ from Dr. Seiler as to the greatest diameter of the tonsils being horizontal. He believes it to be vertical.

Melancholia Cured by Intra-nasal Operation.—Case reported by Dr. Bosworth, of New York. Patient was a male, aged forty-two years, who became melancholy, sleepless, and unfitted for business; complaining of a bursting pain between the eyes and a feeling as if the eyeballs were too large for their sockets. He fell into the hands of various physicians, and went through the following ordeal in the hope that each procedure would cure him: Operation for varicocele, wearing of eyeglasses, operation for stricture, castration, circumcision, ligation of internal pudic artery, operation for hemorrhoids, cautery to spine, seton in neck, tenotomy of eye muscles, enucleation of one eye. He finally came into Dr. Bosworth's hands. He found almost complete right nasal occlusion from septal deviation, and an enlarged left middle turbinated with myxomatous degeneration and evidences of ethinoiditis. The removal of all obstructions from the nostrils speedily restored the patient to health.

A Case of Suppurative Ethmoid Disease, Followed by Invasion of the Sphenoidal Sinus, Abscess of the Brain, and Death.—Dr. Bosworth also related a case of the above nature. Patient, male, aged thirty-three, had ethmoid disease with usual symptoms for some years. He then had sudden headache, left facial neuralgia, but no fever, the latter symptoms lasting four days. General condition good. Pus was seen running down between the left middle turbinated and the septum. These last symptoms were held to indicate extension of the suppuration to the sphenoidal sinus. The use of the gouge and burr afforded but temporary relief, and very speedily he had a rigor fever (106°), semi-coma, paralysis of left face and arm, and died in twenty-four hours. No autopsy was held, but it was believed that death was caused by abscess at the base of the brain. Dr. Bosworth desired to say that ethmoid disease, though generally considered not fatal, might indirectly become so by serving as a focus of infection for the sphenoid. He believed that the so-called cases of sphenoidal disease are probably not truly so, but are rather ethmoidal than sphenoidal. He had seen a hundred and fifty cases of ethmoidal disease, but only two of independent sphenoid disease.

A Further Contribution to the Study of Suppurative Disease of the Accessory Sinuses, with Reports of Cases.—A paper with this title was read by Dr. J. H. Bryan, of Washington, D.C.

Case I. *Abscess of Right Maxillary Sinus, from Dental Caries.*—Patient, male, aged thirty-nine. Symptoms, nasal discharge, more on right side, neuralgia, some emaciation, mental incapacity, and gastric disturbance. On examination some tenderness over canine fossa, slight inferior turbinated hypertrophy, and foul pus discharged by forcible blowing; caries of first and second right upper molars. Removal of one molar disclosed a needle sticking in its root. Patient recollected that he had picked the tooth eight years before with a needle, and that the latter had broken off. Sinus washed out with hydrogen peroxide, and boric-acid solution thrown in, and in the course of three weeks pus had ceased to flow, and alveolar opening was allowed to close.

Case II. *Suppurating Ethmoiditis Terminating in Caries of Anterior Ethmoidal Cells.*—Patient, male, aged sixty-eight. For ten years neuralgia over inner

angle; left orbit always more acid by a coryza. Yellowish secretion from left nostril. No orbital swelling or visual disturbance; left middle turbinated bone enlarged and pus flowing down from below and above it; probe easily detected caries of anterior ethmoid cells, though the swollen mucosa prevented inspection. All diseased bone was curetted away under cocaine; relief of all symptoms.

Case III. *Abscess of Left Frontal Sinus, Resulting Nasal Polypi and Hypertrophic Rhinitis.*—Patient, male, aged fifty, with left nasal discharge for some years, left frontal headache, obstruction to left nostril in breathing, and much impairment of the general health, skin over left frontal sinus was somewhat swollen and red, with pain on pressure. Right inferior turbinated body hypertrophied; left nasal chamber blocked by numerous polypi, with adhesion between left inferior turbinated and septum. Polypi removed, adhesion broken away, and turbinated hypertrophies reduced. This sufficed to drain the frontal sinus, owing to the unusual size of the fronto-nasal duct; result, great relief, but not at time of writing entirely cured.

Case IV. *Abscess of the Frontal, Ethmoidal, and Maxillary Sinuses, with Caries of Fronto-ethmoidal Cells.*—Patient, female, aged forty-eight, subject to frequent catarrhs, and for past seven months left nasal discharge: teeth sound, but those on left upper jaw project farther than their opposites; severe headaches and left facial neuralgias; left side face congested, with supra- and infra-orbital swellings, pain on pressure over these regions and also over canine fossa: right inferior turbinated slightly enlarged, but on left side both inferior and middle turbinated bodies were congested and swollen, and the nose filled with pus, which flowed freely anteriorly and posteriorly.

Translumination showed opacities over left frontal and on axillary sinuses. Visual field was narrowed for red and green. Trephining was done through its alveolar process after extraction of the first molar tooth. Gelatinous mucus escaped; boric-acid irrigation and later daily washings with hydrogen peroxide; all these procedures gave but partial relief, and it was found necessary to open the frontal sinus, from which dark-green and fetid pus was removed. Healing occurred in about a month and the patient was about to be discharged, when the purulent flow with attendant symptoms reappeared. Sinus was again opened thoroughly, curetted, and packed with iodoform gauze. Later it was discovered that communication existed between the frontal and maxillary sinuses. Still later diseased bone was detected about the anterior ethmoid cells. After curetting the latter a cure finally resulted after ten months' treatment.

According to Dr. Bryan, not only is grippe a frequent mark for these sinus diseases, but they are far from being uncommon in simple rhinitis.

After enumerating the causes of frontal and ethmoidal disease, the writer discussed the question of diagnosis of the latter affections. As symptoms of ethmoid disease we may have pain pressure, exophthalmus, usual disturbances, and a softening of the bone at the inner angle of the orbit. Probing through the nose will in the majority of cases detect carious bone.

In frontal disease, the severity of symptoms depends largely on whether the frontal nasal duct is opened or closed; pain is early and severe; tenderness on pressure is frequent, with occasional supra-orbital redness and swelling and purulent discharge in the nostril; but if the fronto-nasal duct is closed, the evidences of local pressure in the neighborhood of the sinus become very great. Orbital or even intra-cranial abscess may result unless early relief is afforded.

As to the treatment of the ethmoidal cases, we should remove the cap of the middle turbinated with a snare or burr, and then continue the opening of the individual cells with some easily controlled instrument, for we are working in a dangerous region. "Free drainage" is the goal of all our efforts. If the frontal-ethmoidal cells are involved we should proceed as in frontal disease. The nose should be freed of anything which seems to clog up the fronto-nasal duct. Incision may be made just below the supra-orbital ridge in the usual manner, and great care be used in determining whether the two frontal sinuses communicate with each other. If the duct is closed or the fronto-ethmoidal cells are implicated in the suppurative process, the little finger should be crowded into the nostril of the affected side, and on this as a guide, a curved trocar should be thrust through the opening in the sinus into the nose.

The two foregoing papers elicited a lively discussion. Dr. Wright gave his experience with a very obstinate case of antral disease. It was often difficult to find out just where the pus came from. He cautioned against too early operation.

Dr. Ingals had seen three cases of sphenoidal disease. He preferred to open into the sinus on its inferior rather than its anterior aspect.

Dr. Gleitsmann preferred to enter the sphenoidal sinus with Schaeffer's probe passed in the usual way. In one case he had had profuse secondary hemorrhage. He passed the probe four and a half inches up and back just along the edge of the middle turbinated, one-eighth of an inch above its lower border. In chronic cases the anterior sinus wall is not very hard, and can be easily broken through with the probe.

Dr. Shurly was surprised to notice that none of the speakers had alluded to disturbances of smell in these cases. He had seen many cases of nasal discharge which he referred to a neuritis of the olfactory bulb, secondary to organic brain disease, but had not regarded them as ethmoid cases.

Dr. Daly would sever the nose along the ala on one side and lay it over on the face before attacking the sphenoidal sinus.

Dr. Mulhall thought the brain cavity was better guarded from injury in the sphenoidal than in the ethmoidal region. Sphenoidal disease apart from ethmoid was rare. Grünwald's monograph was incomparably the best book on the subject.

An exciting discussion followed as to the linear distance into the sphenoidal sinus. Various opinions were given, but no one was able from personal experience to lay down decisive data. Grünwald's measurements are the correct ones.

A Consideration of Some of the More Important Principles.—Dr. W. K. Simpson, of New York, said that the history of advance in any specialty was the history of its surgery. The more we could apply general surgical principles to morbid conditions, the greater would be our success. Conservative surgery may be defined as "knowing when not to interfere." But intra-nasal surgery has gone too far and the pendulum is now returning to a median position. Mistakes have been made, but they should be our landmarks and thus prevent a repetition of our errors.

The writer called special attention, however, to the treatment of obstructive or hypertrophic rhinitis by reducing measures. The nose has a natural protective office toward the rest of the body, and there is in its pathology a pre-surgical or pre-operative period. During this, we should do as much as possible in a therapeutic way with climate, diet, clothing, environment. Where we have conditions of hypertrophy and atrophy with a tendency of the latter to spread, we should be especially chary in our surgical interference, or we may hasten the atrophic changes; remembering also that perfectly symmetrical nasal interiors are rarely encountered.

Our choice of means should eliminate as much as possible shock, leave a smooth, hard mucosa, destroy as little membrane as is consistent with the attainment of the desired result, be attended with a minimum of hemorrhage, and of danger of infection, and finally leave a normal secreting surface. Of just as much im-

portance is the post-operative care of these cases, in which a rigid antiseptic routine should be carried out. Nasal surgeons are apt to get careless in their minor work as to antisepsis. Special care should be taken to clean the thumb and forefinger of the left hand, as with these the commonly employed cotton carrier is rolled. Nasal asepsis is probably impossible, as the nose is not a closed cavity, but we should approximate thereto as closely as possible. Many of the so-called "heavy colds," "grippe" attacks after nasal operations, are nothing but mild sepsis.

Dr. Mulhall thought that danger of septic trouble was greatly lessened if we used the galvano-cautery (when applicable) at a white heat, and never allowed it to cool in situ. He used cocaine four per cent. over the entire nostril and ten per cent. over the operative site. The smarting produced by the radiated heat was immediately relieved by a saturated solution of bicarbonate of soda.

Dr. Wright said that while formerly he had no trouble with noses after the cautery, he found he did not remove much tissue. A more thorough cauterizative plan had, however, given some annoying sequelæ. Trichloracetic acid had been suggested as a suitable application after the operation.

Ludwig's Angina was the title of the following paper, by Dr. J. E. Newcomb, of New York. The writer traced the history of this affection as it has been referred to in the medical literature of the past sixty years. The name itself is objectionable on the ground that pathological processes should be known, not by the name of any person, but by their distinguishing characteristics. Moreover it is probable that Heim, thirteen years before Ludwig, had already noticed this peculiar condition. The modern conception of the affection is to regard it as a diffuse phlegmonous inflammation of the floor of the mouth and of the intermuscular and sub-cutaneous cellular tissue of the submaxillary region, which may resolve or may end in gangrene or abscess. Many writers confine the field of its occurrence to the sub-maxillary region, but this is not in accord with the earlier views. It is quite evident also that all authorities have not had exactly the same thing in mind when using this title.

It has always been a matter of dispute whether the disease should be regarded as a morbid entity deserving a special name and special consideration, or not. Ludwig gave as the characteristic local features the following: 1, A peculiar wooden-like induration of the connective tissue which would not receive impressions; 2, a uniform spread of this induration in such a way that it is always sharply bordered by a zone of entirely unaffected cellular tissue; 3, a hard swelling under the tongue with a bolster-like swelling around the interior of the lower jaw of a deep-red or bluish-red color.

Out of the various confusing statements given, it would seem that the true view is to regard the malady as an intensely infectious phlegmon, occurring under peculiar conditions. It is, in fact, one form of septic sore throat. Etiologically we are in doubt, for the bacteriology is very meagre thus far, and only the ordinary germs of suppuration have been found, though the suggestion of actinomycosis has been made. In the fatal cases there is a uniform record of general disintegration of the cervical cellular tissue and muscular substance. Large sloughs have been found mixed with an ichorous fluid or offensive pus. In several instances the pus has burrowed down along the planes of cellular tissue to the sternum, mediastinum, and even pericardium.

The nature of the infection is a very indefinite one in many instances. All lesions of the teeth, glands of the mouth, herpetic ulcerations of the lips, eruptions of the wisdom teeth, and tonsillitis act as predisposing causes, for they favor the entrance of the virulent germs into the lymphatics, and the conveyance thereby into the cellular tissues. Cold as an exciting cause signifies very little, for what is called "cold" is often an indeterminable infection.

In all these cases the pus originates in the triangular pyramidal space the apex of which (situated below) corresponds to the point where the mylo-hyoid muscle borders the genio-glossus and the base of which (situated above) stretches along under the tongue. Its external wall, which is oblique, is formed by the internal face of the inferior maxilla and the mylo-hyoid muscle; the internal wall (vertical) by the genio-glossus and hyglossus. Undoubtedly the sub-lingual gland often first becomes affected and the sub-maxillary later. The germs determining the sub-lingual phlegmasia may penetrate the sheath of the sub-maxillary gland also, or the sub-lingual pus may disassociate the fibres of the mylo-hyoid muscle and thus invade the sub-maxillary region.

The local symptoms are those of a phlegmon, and the constitutional may assume either a sthenic or asthenic type of an infectious fever. Special importance is attached to the presence at the inner aspect of the dental arcade of a pad-like or button-like area of hardness.

A differential diagnosis must be made from osteomyelitis of the jaw, simple sub-maxillary adenophlegmon, and that rare condition known as Fleischman's hygroma.

About 100 cases are on record under the title of Ludwig's disease, but in only 58 are the particulars given with sufficient fulness to serve for analysis. Of these, 44 were males, 9 females, and 5 infants (sex not stated). The oldest patient was sixty-six years of age, and the youngest three months. Forty per cent. occurred between the years of twenty and thirty. Of the 58, recovery is noted in 33 and death in 25. In 9 only were bacteriological findings recorded, viz., streptococci pyogenes, 4; staphylococcus pyogenes aureus and albus, each 1, and cocci of erysipelas, 2. In one the microbe was a little longer and narrower than the B. coli communis, but clearly distinguishable from the latter by culture reaction.

Treatment is summed up in early incision, subsequent rigid antisepsis, and general supportive measures.

Very recently Semon, of London, has advanced the view that this malady, along with erysipelas of the pharynx, acute œdematous laryngitis, œdema of the larynx, and phlegmonous pharyngitis, are all practically one and the same thing, viz., septic inflammation of the throat, differing only in severity and localization, and having the same etiology. His general statement is that this theory constitutes a simple clinical application of bacteriological principles to a certain group of septic inflammations.

The paper was discussed by Drs. Daly and Ash, both of whom related cases thought to be of this nature. Dr. Swain thought that peri-tonsillar inflammation at the base of the tongue might produce the same type of symptoms.

Tuberculosis of the Upper Air-passages.—The session ended with a discussion on this topic opened by Dr. Jonathan Wright, of Brooklyn, who spoke of etiology. Recent bacteriological progress has led us to modify very largely the literal interpretation of Koch's postulates regarding the relations of germs to disease. We now know that bacteria can get through epithelium and in some instances they seem to be destroyed by phagocytosis. It is believed possible that the lymphoid tissue at the base of the tongue may become inoculated by tubercular material taken in as food. It is conjectural, however, as to whether the bacilli found here are really in the tissues or in the superficial papillæ. We can inject tuberculous material into animals and kill them, but the Pravaz syringe does not exactly meet the requirements of clinical medicine. We all get a dosage of tubercle bacilli sooner or later, and one in every seven falls. Autopsies reveal in one out of

every two or three evidences of arrested tuberculosis. The mortality is due not so much to the bacillus as to the bad general environment under which men live. Physicians as a class are not particularly liable to tubercular disease, though exposed most constantly thereto. Children fed on the milk of Alderney cows suffer especially.

The scanty anastomosis between the external and internal lymphatics about the neck explains perhaps why so many escape, but in the nose the abundant communication of the lymph-channels with those of the sub-arachnoid space may account for the frequency in children of tubercular meningitis. The protection of the larynx is also very remarkable. We have abandoned Louis's theory of corrosive sputa, but many patients are either not examined, or the tubercular deposit escapes observation, or the tubercular ulcers are seen only when the patient is in extremis. Out of 25 cases examined, Dr. Wright found nasal or throat tuberculosis in only 4. As we clinically see the disease, the pyogenic cocci may first make a breach in the epithelium through which the bacillus enters. The latter cannot produce an abscess. It is doubtful whether it can penetrate glandular epithelium or not.

Sections of the laryngeal mucosa in recently born children show that it has a wavy outline, especially in the inter-arytenoid space. Under vocal strain this wavy columnar epithelium stretches, and so exercises a protective influence over the deeper laryngeal structures. Nasal tuberculosis in phthisis generally comes toward the end of the disease, as does that of the pharynx, though the latter is possible in the earlier stages of acute miliary tuberculosis.

Dr. C. C. Rice, of New York, was expected to speak on diagnosis, but was not present. The following is an abstract of his paper :

Tuberculosis of the Nares is Rare.—Williglk found only one case in 476 autopsies. It may occur either as an ulceration on the nasal septum and floor, and resembling tubercular ulcerations in general, or as small papillary growths attached to the turbinated tissues. Nasal tuberculosis is frequently overlooked, since it may co-exist with septal specific disease, and because the small growths frequently removed are not examined. In any case of chronic ulceration in a patient with pulmonary disease, we should be suspicious if the nasal condition resists the effect of the iodide.

Tuberculosis of the Pharynx and Larynx.—In Willigk's 1,307 autopsies, the latter was involved 237 times and the pharynx only once. Rice believes that tuberculosis of the fauces is usually associated with an acute general tuberculosis rather than the customary chronic lung process. Occasionally miliary nodules may appear in the soft palate before it undergoes ulceration, but probably all organs are affected at the same time.

Tuberculosis of the Larynx.—The writer further believes that eighty per cent. of all cases of laryngeal phthisis can be easily diagnosed, but that great care needs to be exercised in the remaining twenty per cent. Of this latter proportion, perhaps one-half cannot be definitely diagnosed without the aid of the iodide and the microscope. In ordinary cases nothing can be more typical than the semi-œdematous, semi-inflammatory swelling of the tubercular infiltrations, and the superficial "moth-eaten" ulcer which follows with its gray surface. Such lesions are usually symmetrical and upon a very anæmic surface.

In the laryngeal appearances in incipient tuberculosis, we find localized anæmias of the hard and soft palate in an otherwise healthy pharynx, and, with this, enlarged capillaries merging from the different portions of the palate toward the uvula. In addition, we have elevation of the papillary layer in the inter-arytenoid commissure and feeble action of the internal laryngeal adductors. Recurring papilloma on the vocal band is to be regarded as a suspicious circumstance. Rice believes that there is often an intimate relation between them and tubercular laryngitis. Suspicious also is localized congestion of the arytenoid cartilages or the slightest appearance of bogginess.

There are also irregular cases. We frequently have the co-existence of syphilitic and tubercular ulcerations, and specific disease in the larynx with tubercle in the lungs.

One or two cases were cited presenting that pathological condition common enough to syphilis, but very rarely seen in tuberculosis, viz., adhesive inflammation at the anterior ends of the vocal bands. Also cases illustrating three forms of growths seen at times in the tubercular throats : 1, The granular hyperplasias which are the ordinary granulation tissue ; 2, the wart-like excrescences frequently seen in the inter-arytenoid commissure, and which are closely allied to the laryngeal papillomata; and, 3, the small round tubercular tumors appearing beneath unbroken mucous membrane, microscopically found to consist of a tubercular structure usually containing tubercle bacilli.

Dr. E. L. Shurly, of Detroit, spoke on "treatment," and enumerated various remedies which have been used in the disease. He believes we may have a phthisis without tuberculosis, and is inclined to doubt whether the post-mortem table reveals evidences of previous bacillary invasion as often as is claimed. The best local remedies he has found have been chlorine gas, solutions of sodium formate, and iodoform. As a specific internal, plain iodine with chloride of gold and sodium have accomplished good results. He would pay great attention to diet, and in painful swallowing would use gavage. He made the point that vegetable food should be combined with the meat extracts in these cases. In the laryngeal cases alcohol was apt to be too irritating. We should not take away all hope from our patients, and when they get so low we should use morphine enough to keep them comfortable. Tracheotomy, scarifying, and curetting he did not believe in.

Surgical Treatment of Laryngeal Tuberculosis.—This subdivision of the general topic was discussed by Dr. J. W. Gleitsmann, of New York. He confined his remarks to curettement with the single or double instrument. Surgical treatment is, broadly speaking, either endo- or extra-laryngeal. Under the former are included incision with knife or properly curved scissors, curettement, sub-mucous injections, electrolysis, and the galvano-cautery ; under the latter laryngotomy and excision of diseased parts, extirpation of the larynx, and tracheotomy ; altogether eight subdivisions.

A *résumé* was given of the historical aspects of the subject. Dr. Gleitsmann has found recorded eight total and seven partial extirpations of the larynx for tubercular disease. In four of the former category, diagnosis was made before operation, two were done on account of lupus, and two had been diagnosed as carcinoma. In the latter class, five operations were done for tuberculosis, one for lupus, and one for supposed carcinoma.

As to curettement, it is steadily gaining in favor. Only six out of seventy publications consulted are indifferent or do oppose it. We cannot hope that it will exert a favorable influence on the almost always present pulmonary complication, but we are justified in speaking of a cure of the larynx where, in spite of the continuance of the pulmonary disease, the laryngeal symptoms have subsided ; when the larynx bears a normal aspect, and furthermore, when there is no trace of the local disease found at post-mortem examination—conditions which are established beyond a doubt and which are on record in literature. Relapses may occur, for curettement cannot of course remove the diathesis nor can any other plan of treatment.

Two writers claim to have observed outbreak and hastening of the pulmonary process after operation, but this is probably a coincidence and does not prove any causative relation. Other objections are danger of

hemorrhage, pain, and difficulty of operating. Bleeding can be arrested by a styptic solution of lactic acid and liquor ferri chloridi; pain can be almost entirely avoided by the repeated applications of strong solutions of cocaine, and the remedy may be injected directly into the tissues. Difficulty in operating can never be considered a valid objection against any legitimate surgical procedure.

Curettement should be regarded as analogous to excision by the surgeon of a tuberculous joint. It removes a diseased area, a focus of infection which is a constant drain upon an already debilitated system. It is in properly selected cases more effective, quicker, and better in result than any other procedure. Besides, the infiltration of the arytenoid region, which is the great cause of dysphagia, can often be removed at one sitting by the double curette. Healing is prompt and cicatrization rapid. Moreover, the suffering of patients due to abundant nerve proliferation, justifies arytenoidectomy. Even in active pulmonary disease with hectic, diminution of dysphagia means more nourishment taken and a consequent improvement in the general condition. Additional advantages gained are improvement in voice, cough, and respiration.

Indications for curettement are :

1. Primary tubercular disease without lung complication.

2. Cases with concomitant lung disease, either incipient or which has stopped short of softening or hectic.

3. Especially circumscribed ulcerations and infiltrations.

4. Dense hard swelling of the arytenoid region, ventricular band, posterior wall, tuberculous tumors, and affections of the epiglottis.

5. In advanced lung disease with distressing dysphagia from arytenoid infiltration.

Contra-indications are :

1. Advanced pulmonary disease and hectic.

2. Disseminated tubercular disease of the larynx leaving little or no area of healthy tissue.

3. Extensive infiltration producing stenosis. Here tracheotomy is indicated.

As to technique. Heryng's single curettes are best suited for cleaning and scraping of ulcerations: Krause's double curettes and Heryng's rotary curettes for excision of tubercular infiltration. Sub-glottic lesions can be operated upon with Scheinmann's forceps, and an attempt may be made to reach the ventricles of the larynx with laterally bent forceps. Absolute quiet is necessary after operation, and until cicatrization is complete daily applications should be made of lactic acid and pyoktannin (one or two per cent.). Cicatrization occurs in from seven to twenty-eight days. Ulcerations which are well defined do better than if shallow and extended. Dense infiltrations (which are generally localized) do better than œdematous conditions.

After giving the statistics of Heryng, Gougenheim, and Krause, with their four hundred and fifty-five cases, Dr. Gleitsmann narrated his personal experience with the double curette in twelve, all with lung complication; two operations were for infiltration of the posterior wall alone, one for such with affection of the ventricular band combined; four were arytenoidectomies, three arytenoidectomies and excision of the ventricular band, and two of the latter alone. Arytenoidectomy was necessary a second time with two patients on account of recurring infiltration. One patient died from heart failure and another from advanced lung disease. Four are without recurrence of laryngeal disease from six to ten months. Of these, one had an affection of the posterior wall, another of ventricular bands, and two of the arytenoid region.

THIRD DAY, WEDNESDAY, JUNE 19, 1895.

Tuberculosis of the Upper Air-passages.—This discussion was continued.

DR. T. MORRIS MURRAY, of Washington, D. C., had used lactic acid in seven or eight cases of laryngeal and pharyngeal ulcers, and had seen good results in three. One case was curetted two weeks before the patient's death. The uvula was also infiltrated in this case. The ulcer had healed and the patient's last days had been rendered much more comfortable. One case had remained healed now for five years.

DR. INGALS thought that of one thousand cases operated on and one thousand cases treated topically, the latter series would show more cures than the former. He had had four recoveries from laryngeal and pharyngeal ulcerations by simply rubbing in lactic acid without previous scraping. In the deeper cases we should doubtless curette. It was of doubtful propriety to cut away large masses of tissue. The trichloride of iodine (gr. j. to ij. to water ℥ j.) had served him well. He did not like to use cocaine here on account of its depressing effects upon the nervous system. The patient is not so able to bear pain afterward. His favorite mixture is one of carbolic and tannic acids with morphine. It smarts at first, but there is no pain afterward.

DR. DALY had seen some laryngeal cases recover under diet, inhalations, and especially iodoform, with which he saturates the patient. He has never curetted, thinking it useless so to do. He had used creosote in large doses.

DR. WRIGHT, in closing the discussion, said that he was very sceptical as to the treatment of laryngeal tuberculosis. Ulcers will occasionally heal under curettement and lactic acid. We have been looking too much at one single etiological factor, whereas there are many. Laryngeal tuberculosis may give no symptom whatever even when the erosive process has gone way down to the cartilage. The cases reported cured have been limited to the first stage of the disease.

Very few cases out of the whole number are suitable for Krause's and Heryng's methods.

DR. SHURLY had tried Dr. Ingals's sedative formula, but had great difficulty in making a good mixture of the three ingredients, and used them separately. As to creosote, he felt disappointed in it, but thought it a good, mild, and disinfecting agent. Has had no experience with the curette. It seemed absurd to expect recovery by scraping a few ulcers while there were ulcerated patches on invisible areas.

Necrosis of the Middle Turbinate.— Paper by DR. A. B. THRASHER, of Cincinnati. While in acute rhinitis the lower turbinate is more frequently affected, yet disease of the middle is more significant, in that the pressure on the adjacent walls is great and the mouths of all the adjacent sinuses are easily closed, thus causing a mechanical retention of the normal secretions, which quickly became purulent.

Ethmoiditis is comparatively a frequent disease, but necrosis of the middle turbinate is certainly rare. Zuckerkandl declares he has never seen it. Woakes asserts that necrosis is present as a rule wherever there is ethmoiditis, but the pathologist's report of his published cases gives only two cases of true necrosis out of twenty alleged to be such.

Dr. Thrasher sees no reason why prolonged disease of the middle bone should not eventuate in necrosis, as the local anatomical conditions all would appear to favor such a result. Given a case of ethmoiditis and a polyp springing from under the middle turbinated, the conditions are certainly fairly ripe for developing necrosis of the latter structure. On the other hand, it is possible that a polyp may spring from a membrane bathed in the secretions from a purulent ethmoiditis. It is quite analogous to the condition of aural polypi from purulent otitis media. Cysts of the bone do not necessarily lead to necrosis.

Dr. Thrasher gave the two following clinical histories :

CASE I.—Woman with severe pain in left side of nose,

radiating over entire left face and head, constant though with regular and intense exacerbations; left side nose slightly swollen. Creamy discharge flowed from beneath left middle turbinated bone with an offensive odor, but not that of necrosed bone; anterior extremity of left middle turbinate swollen and pressing on septum and lower turbinate. Patient had severe influenza one year before.

Treatment.—Removal by cold snare of projecting mass, about one inch long by one-third inch in vertical, and one-quarter inch in lateral diameter; mucosa was tightly drawn over bone, and one-third of outer portion of latter was dead. Adjacent ethmoid cells were curetted. No recurrence in four years.

Case II.—Male, aged twenty-six. Neuralgia right supra- and infra-orbital nerves for two years, unrelieved by medical treatment; right middle turbinated presenting as a large rounded mass pushing out outer wall of nose and filling middle meatus; little discharge.

Treatment.—Cold snare broke down tissue (in an endeavor to remove *en masse*), leaving a large open cavity within their walls. A part of bony tissue removed bore evidence of being dead. No connection could be made out between opened cyst and ethmoid cells.

The general symptoms of the condition are: 1, Pain, referred to supra- or infra-orbital regions, orbit itself (ethmoid involvement), or ear; 2, discharge often offensive; 3, nasal obstruction and anosmia, but frequently, even in severe disease of the middle turbinate, the breathing is unobstructed; 4, obstruction of natural sinus openings with attendant symptoms; 5, external nasal deformity and displacement (in ethmoid cases) of globe of the eye; 6, various reflex disturbances.

Treatment.—In cases of middle turbinate inflammation, if mild and recent, use alkaline sprays, cocaine, scarification, or deep incision; if the case is of long standing and osteitis or necrotic bones are suspected, prompt removal of the offending tissue is advocated. This may be done by cold snare, drill, trephine, or saw-tooth scissors. Cauterization here is contra-indicated owing to the proximity of the brain.

Dr. Thrasher also reported a case of congenital osseous stenosis of the naris. Patient, male infant, eighteen months of age; in good condition but with mouth breathing and muco-purulent flow from right naris. Adenoids were found in the vault and removed, but a probe passed through the nostril detected a thin partition of bone just at the posterior naris. This thin scale, thicker toward the septum and thinning out toward the external wall, was seemingly united to the latter at the posterior extremity of the lower turbinate, but was not attached to the turbinate, as could be detected by the finger in the naso-pharynx.

Dr. S. W. Langmaid, of Boston, had seen three cases of congenital closure of the nares. He thought that the temporary continuance of mouth-breathing after operation was due to the incapacity of the nose for immediate functional activity until it had been trained, so to speak.

Dr. Ingals had never seen any congenital cases. He thought that in many cases of adenoids there was a partial closure of the posterior nares which was overlooked. He always probes both nostrils before the patient comes out from under the anæsthetic, to see if they are pervious.

Cysts of the Naso- and Oro-pharynx and Fibroma Papillare, or True Papilloma of the Nasal Septum.—Dr. Jonathan Wright, of Brooklyn, described cases of this nature and presented illustrative drawings. Naso-pharyngeal cysts are very rare, and sinuses of the naso-pharyngeal mucosa are not very common, though Tornwaldt has asserted the contrary. The so-called pharyngeal "crusa" and the cysts are formed by the agglutination of the folds and projections of the membrane found in infancy. Hence results a closed cavity leading to discharge of, or retention of, thick mucus, which dilates the walled-in space to the proportions of a cyst.

The epithelium in the naso-pharynx is columnar, but shades off below into the squamous, and in many cases of hypertrophied lymphoid growths in the vault this covering is in part or wholly of squamous cells, evidently the result of irritation from secretions or rubbing surfaces. The cyst reported in the present paper is probably an inclusion cyst. In a transverse section through folds of the mucous membrane in the naso-pharynx of a still-born child, it is possible to see oblong spaces either just where the lymphoid tissue borders on the connective tissue, or just within the lymph tissue itself, or just within the connective tissue. These spaces are lined with a single endothelial layer. These are probably lymph-spaces and from them cysts can probably originate.

The nasal papilloma was removed from the septum of a Roumanian woman, aged twenty-eight, with a history of nasal obstruction for seven years. Just inside the left nostril was a soft, vascular, pedunculated mass freely movable. The cold snare removed it with only moderate hemorrhage. The site of attachment was the upper part of the cartilaginous septum about 2 ctm. from the columna. This spot corresponded with a region subjected to the attrition of the upper edge of the triangular cartilage, forming the ridge known as the *plica vestibuli*, and which in this case rubbed against the septum when the lower edge of the triangular cartilage was rolled out by muscular action in the dilatation of the ala nasi during inspiration. The base was cauterized and there has been no recurrence (nine months).

Microscopical examination showed the neoplasm to be a true fibroma papillare.

Dr. Newcomb had recently removed with the cold snare without hemorrhage a naso-pharyngeal cyst from a young man of about twenty. There was still left a mass *in situ*, and he presumed he had a multilocular condition to deal with.

Dr. Langmaid had recently removed a naso-pharyngeal cyst by avulsion, the attachments of the growth being such that the wire loop could not be made to encircle it. No hemorrhage resulted. In cases of recurrence of such growths, it was possible that we left a portion of the cyst wall behind.

Relation of Vasomotor Disturbances to Diseases of the Upper Air-tract.—This question was discussed by Dr. W. H. Daly, of Pittsburg, who reiterated his well-known teachings on this subject. He called attention also to a variety of disturbance first described by Glascow, where the mucosa is pallid and yet leaks serum. As to his own success in relieving asthma and hay-fever by intra-nasal treatment, he would simply say that his own statistics showed a cure in sixty-three per cent. of catarrh and hay-fever cases, and in forty per cent. of spasmodic asthma. He would conclude: 1. That abnormal disturbances of vasomotor origin may be primary or secondary. 2. That both may be co-active and progressive. 3. That the surest and quickest relief is afforded by those cases where surgical interference finds its proper election.

Dr. Mulhall remarked that as to vasomotor disturbance, there was the pallid variety and the turgescent, just as some people get white in the face when angry and others red. The mode of life was a frequent factor in such cases, rather than any essential intra-nasal condition. Diet and exercise would do much to relieve them. He advocated daily frictions with cold water, mild galvanism, a daily dosage of atropia, one to twenty grains, given in the morning on an empty stomach, with one drop of Fowler's solution after meals.

Dr. Simpson was inclined to lay less stress than formerly on the reflex disturbance theory, as he had seen so many cases in which a thorough examination of the entire body had revealed causes of disturbance supposed at first to originate in the nose. He believed

that it would be found in most instances the cause was near the seat of the disease we had to treat.

The Cigarette Habit.—This was the title of the closing paper, read by Dr. J. C. Mulhall, of St. Louis. The chewer, smoker, and snuff-taker all experience a different variety of satisfaction. The cigarette smoker soon learns to inhale the smoke, an unusual habit with either cigar or pipe smokers. The smoke does not penetrate farther than the first division of the bronchi. It does not reach the lungs proper. It enters into the tidal but not the residual air. A cigarette milder than the one habitually used does not give the usual satisfactory feeling to the laryngeal and tracheal interior, nor also does one stronger than usual. The effect of inhalation is really a pleasurable sensation produced upon the laryngeal and tracheal filaments of the pneumogastric nerve, a sort of nicotine satisfaction. The absorption of material from smoke varies, of course, according to amount of surface, and it has been estimated that in inhalers there is three times as much absorptive surface as in non-inhalers. Three cigarettes are about equal in tobacco strength to one cigar, but it is the frequency with which cigarettes are smoked which has led to the characterization of the habit as "deadly." Moreover, the circulative effect of frequent cigarettes is analogous to that of a given amount of drug administered in divided doses.

The evils of cigarette smoking are local and constitutional. The latter are the same as from the use of tobacco in any form—always nicotinism—and on the young these evils are great. Cigarettes are so cheap that they may be said to teach the use of tobacco. The first cigarette never nauseates as does the first cigar, and hence the deterring effect of the latter is wanting.

As to local effect, cigarettes may aggravate pre-existing trouble, but Dr. Mulhall does not believe that there is evidence to prove that they originate any throat disease worthy of the name. There may be a mild hyperæmia of the mucosa, or even a trifling catarrh, with pearly viscid secretion ejected by a single slight cough in the form of pellets. A few râles wholly bronchial are occasionally heard. The murderer Maxwell, confined in a St. Louis jail, inhaled forty cigarettes daily, and though he was a complete physical wreck, he had no throat alterations, as was proven by an examination of the parts made after death. Mario, the great singer, was an inveterate inhaler.

Dr. Ingals, in discussing the paper, said that he could not assent to the doctrine of the local harmlessness of tobacco. He has seen pronounced tracheal cough result from its use.

Dr. Carl Seiler stated that the habit of spitting while smoking did more local harm than the smoke itself, because the constant loss of saliva led to an abnormal dryness of the pharynx.

Dr. Langmaid thought that one great injury of tobacco upon the young was in its destruction of the power of consecutive thought, by reason of its insidious narcotism. As to pipe-smoking, it was not so harmless as generally believed, because the mouth was kept hot by the heat of the stem and the relatively large mass of fire in the bowl.

During the session of the Congress the following papers were read by title :

"Foreign Bodies in the Œsophagus," by Dr. Harrison Allen, of Philadelphia. "The Influence of Chronic Diseases of the Throat Upon Certain Defects of Speech," by Dr. D. Bryson Delavan, of New York. "Cyst of the Maxillary Sinus," by Dr. Charles H. Knight, of New York. "Pemphigus of the Pharynx and Larynx," by Dr. M. R. Brown, of Chicago. "Compensatory Arytenoid Movement," by Dr. William Porter, of St. Louis. "A Study in Diphtheria," by Dr. S. Hartwell Chapman, of New Haven.

At an executive session the following gentlemen were admitted to active fellowship :

J. E. Boylan, M.D., Cincinnati, Thesis, "Herpes Chronica Pharyngis ;" F. E. Hopkins, M.D., New York, "Œdema of the Larynx and Report of a Case." Thomas Hubbard, M.D., Toledo, "Treatment of Acute Laryngitis." J. E. H. Nichols, M.D., "Intra-nasal Causes of Headache."

The next meeting will be at Pittsburg, Pa., the time to be selected by the Council. The following officers were elected for the ensuing year : *President*, Dr. W. H. Daly, Pittsburg. *First Vice-President*, Dr. Jonathan Wright, Brooklyn. *Second Vice-President*, Dr. A. W. de Roaldes, New Orleans. *Secretary and Treasurer*, Dr. H. L. Swain, New Haven. *Librarian*, Dr. J. H. Bryan, Washington.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Twenty-ninth Annual Meeting, held at Cape May, June 25 and 26, 1895.

O. H. Sproul, M.D., President, in the Chair.

The Health of New Jersey.—Dr. H. W. Elmer, chairman of the standing committee, read a summary of reports from physicians throughout the State regarding the health of their localities. Typhoid fever had been more common than usual. Antitoxin for diphtheria had been slow of adoption. Three cases of hydrophobia were reported. Variola, which had threatened an outbreak, had been suppressed. The consensus of opinion was in favor of sterilized water for wounds instead of antiseptic solutions.

Prevention of Blindness through Legislative Enactment.—Dr. W. B. Johnson, chairman of the committee on this subject, read the report, by which it appeared that they had succeeded in getting a bill passed by the State Legislature which differed in one or two important points from the one first passed in New York and subsequently by several other States. He quoted a paper by Dr. May showing, apparently, no decrease in blindness from ophthalmia neonatorum in New York since the passage of Howe's bill in 1892. The intentions of the bill were not carried out. The following is a copy of the New Jersey bill, the new features being in italics :

1. Be it enacted *by the Senate and General Assembly of the State of New Jersey*, That should one or both eyes of an infant become inflamed, swollen, or reddened, or show any unnatural discharge at any time within two weeks after its birth, *and no legally-qualified practitioner of medicine be in attendance upon the infant at the time*, it shall be the duty of the midwife, nurse, attendant, or relative having charge of such infant to report the fact in writing, within six hours, *to the local board of health* of the city, township, or other municipality in which the parents of the infant reside.

2. *And be it enacted*, That the said local board of health shall direct the parents or person having charge of such infant suffering from such inflammation, swelling, redness, or unnatural discharge of the eyes, to immediately *place it in charge of a legally-qualified practitioner of medicine*, or in charge of the physician of the city, township, or other municipality if unable to pay for medical services.

3. *And be it enacted*, That every local board of health in the State of New Jersey *shall furnish a copy of this act* to every legally-qualified practitioner of medicine, and to each person who is known to act as a midwife or nurse, in the city, township, or other municipality for which such board of health is appointed ; and the Secretary of State shall cause a sufficient number of copies of this act to be printed, and to supply the same to such officers for distribution.

4. *And be it enacted*, That any failure to comply with the provisions of this act shall be punished by a fine not to exceed two hundred dollars, or imprisonment not to exceed six months, or both, upon conviction

under prosecution proceedings to be brought *by any local board of health.*

5. *And be it enacted,* That this act shall take effect and be in force on the first day of May, one thousand eight hundred and ninety-five.

Dr. Charles Kipp thought the Society was to be congratulated on the passage of this bill. But something should be done to prevent the occurrence of purulent conjunctivitis, and to lead to more general knowledge of the best means of treating it among physicians, and he moved that a committee be appointed to inquire into the best methods for the prevention of purulent conjunctivitis of the new-born in use in hospitals, and to recommend that which they regard as best adapted for private practice. The motion was adopted.

New Jersey on Bovine Tuberculosis.—Dr. J. W. Stickler, chairman of the committee on bovine tuberculosis, stated that he and Dr. A. V. M. Baldwin, members of the committee, had again gone before the committee of the Legislature and advocated the passage of a bill providing for the inspection of herds of cattle throughout the State, and the destruction of such as might be found tuberculous. It was objected to on account of its mandatory character, and the fact that a veterinarian was to be inspector. Of course, without such provisions the law would be worthless, as the present one was proving itself to be. On motion the committee was continued.

Relation of Physician and Pharmacist.—Dr. H. L. Coit, chairman of the committee on this subject, read the report. The following ethical rules had been formulated: Ethical rules for the guidance of physicians and pharmacists in their relations with one another, proposed to be adopted conjointly by the Medical Society of New Jersey and the New Jersey Pharmaceutical Association.

Propositions: 1. Ethical principles, or standards of right conduct, exist, irrespective of their formulation or codification. 2. Ethical rules are calculated to elevate standards of moral conduct and to foster a spirit of harmony between professional men. 3. A code of ethics is designed not only for the restraint of those who are actuated by unworthy motives, but for the guidance of those also who seek to be governed in their actions by high and true principles.

The Duties of the Physician to the Pharmacist.—1. The physician has no moral right to discriminate in favor of one pharmacist to the detriment of another, except for dishonesty, incompetency, or unscientific methods of work. 2. The physician is never justified in receiving from a pharmacist gratuities in return for patronage; in depositing secret formula with an individual pharmacist, or by word or deed to jeopardize his professional reputation. 3. The physician may sometimes find it an advantage to the patient to dispense the medicine, yet in the main it must be regarded as a subterfuge, and a hindrance to all interests involved. The physician should, if practicable, avail himself of the superior technical skill of a trained pharmacist in the preparation and dispensing of medicines.

The Duties of the Pharmacist to the Physician.—4. The pharmacist who recommends drugs or medicines for specific remedial purposes, either directly or through the avenues of advertisement, thereby exceeds the limits of his profession, and commits an act unworthy of his calling. 5. The pharmacist who consents to diagnose disease or prescribe for patients, except where emergencies arise, without the proper medical training, assumes responsibilities for which he is not qualified, and justly incurs the disapproval of physicians. 6. The pharmacist transgresses his true province when, for commercial purposes, he issues to physicians printed matter setting forth the therapeutic indications for the use of drugs or medicinal preparations. The constituents of the drug or compound, together with its chemical and physical properties, should be sufficient guarantee of its utility.

The Duties of the Physician and Pharmacist to the Public.—7. The combined efforts of the physician and pharmacist are required to protect the public from the nostrum maker, pseudo-scientific pharmacist, the sectarian physician, and drug-vender, and the two should be in continual alliance to demand the extermination of these commercial and mercenary institutions. 8. The physician and pharmacist should, as far as possible, limit the multiplication and manufacture of proprietary compounds. It must be regarded as reprehensible to encourage the use of these remedies to the exclusion of those which are official in the pharmacopœias. It is also their plain duty to discourage the use and sale of all medicines which lead to baneful drug habits. 9. The best interests of the patient are undoubtedly conserved by the custom of physicians of practising rational therapeutics, to the exclusion of those methods which tend to the use of many remedies, or those of unknown composition; and the supreme effort of the dispensing pharmacist should be to complete the circle of therapeutics by supplying eligible and trustworthy preparations.

Dr. Coit stated that this proposed code had met with warm approval by the State Pharmaceutical Association, but action had been deferred until the State Medical Society could be heard from. Upon motion, action and discussion were postponed until the next annual meeting. Printed copies were ordered distributed among the district societies for consideration.

Diseases of Pregnancy and Parturition.—The President, Dr. O. H. Sproul, stated that he had not been able to complete the address which he had intended to deliver on this occasion, so at the last moment had prepared a short paper containing a few personal observations on the diseases of pregnancy and parturition, for the crudeness of which he presented his apology.

Referring to the vomiting of pregnancy, out of over two thousand cases of pregnancy which he had attended there was uncontrollable vomiting in but one. This patient became maniacal and died. He would now resort earlier to abortion in a similar case.

Pruritus affecting the genitals, in his experience, usually resulted from vaginitis, and was relieved by douche of boracic-acid solution and subsequent application of nitrate of silver, twenty grains to the ounce. Œdema of the pudenda and extremities was usually relieved by salines. Dr. Sproul performed immediate perineorrhaphy, but left the surgical treatment of lacerations of the cervix, should necessity for this arise, until later. During thirty years' practice he had had but two cases of puerperal fever. It was a rare disease in rural communities. He had never been the agent for conveying erysipelas or other infectious disease. Perhaps this was because the precautions which had been inculcated by his teachers had led him to adopt more than usual cleanliness. In the management of phlegmasia dolens, he had usually been successful with the flannel roller bandage and slightly elevating the limb. In hemorrhoids, if medicinal and palliative measures did not give relief, he resorted to surgical treatment by ligation. Chloroform anæsthesia to the extent of complete insensibility was seldom necessary in labor, and should therefore be avoided.

Some Original Investigations Showing the Antagonism Between Morphine and Cocaine.—Dr. J. W. Stickler, of Orange, read a paper, which will be published in full later, showing that the best antidote for morphine poisoning is cocaine, and *vice versa*. His attention had first been called to the antagonism between the two drugs by a patient taking about eighteen grains of cocaine in solution, and being nervous and unable to sleep afterward, took about half an ounce of laudanum, which in one hour relieved the nervousness and induced sleep. The patient attended to his business next day. Later one of his laboratory assistants gave

to a patient who had taken nearly three ounces of laudanum, three-fourths of a grain of cocaine in divided doses, and within two hours he was perfectly normal. His experiments on dogs and pigeons, and also on two men, showed strikingly the antagonistic effects of cocaine and morphine, and in comparison with aconite and permanganate of potassium, he thought cocaine was a far superior antidote for morphine poisoning. In opium poisoning he would first give an emetic, then one-fourth grain cocaine hypodermatically, repeating it twice at twenty minutes interval if necessary.

Comparative Advantages of Water, Hot or Cold, versus Germicidal Solutions, in Modern Surgery.—Dr. W. B. Johnson opened the discussion upon this subject, which had been presented at the last annual meeting. He pointed out the marked advance which the Listerian system had made possible, but stated that lately the use of chemical agents had come to be so far restricted that water was relied upon as the chief factor, or even the exclusive one, in the preparation of instruments and cleansing the field of operation. The approach to the perfect aseptic technique now attained was undoubtedly due to perfect ablution. The time was not far distant when all chemical agents for the destruction of bacteria would be excluded from use in the vicinity of the wound — asepsis, not antisepsis, being the desideratum, when complete mechanical cleansing with sterilized water would render the use of germicidal solutions unnecessary.

Dr. Mordecai Price, of Philadelphia, said he thought chemical germicides would in the very near future be consigned to oblivion. He was not afraid of bacteria. They found in his work a hotel without a table. Leaving no food for them, his boarders left. There was no question in his mind that bacteria were not the cause of disease, but that disease was the cause of bacteria. Fortunately he had come into surgery after Bautock and Tait had demonstrated that chemical germicides were useless—were worse than useless—for they complicated the disease of which one was trying to relieve the patient. Dr. Price relied on cleanliness.

Dr. Barton, of Philadelphia, employed chemical antiseptics whenever he had to operate where he could not avail himself of the services of his own trained assistants, on whose aseptic methods he could place perfect reliance.

Dr. Ill would agree with Dr. Price, that no antiseptic should be put into the abdominal cavity, but he could see no reason why one should not sterilize the field of operation as well as the hands and instruments.

Dr. Charles Kipp said that antisepsis had made it possible to operate with safety upon a cataract within an hour after one had treated a case of gonorrhœal inflammation of the eye.

The views expressed by Drs. Gross, Keyser, of Philadelphia, and Benjamin, were in accord with those who used antiseptics in addition to cleanliness.

Papers on the relations between physicians and pharmacists were read by Delegates W. C. Alpen and H. P. Reynolds, from the State Pharmaceutical Association.

Our State Medical Society, Its Past Success, and Suggestions Concerning Its Future Usefulness.—Dr. D. C. English, third vice-president, took this subject for his address. As showing the past usefulness of the Society, he mentioned the fact that it had in effect originated the State Board of Health, the State Asylum for the Insane at Trenton, and that at Morris Plains, the New Jersey Pharmaceutical Association, etc. Among the officers of the Society who had been instrumental in its success were: Steven Wicks, William Pierson, who had acted as secretary for twenty-nine successive years, Ezra M. Hunt, and H. R. Baldwin. Two of the oldest and most valuable members were Pennington and Rogers. The society was the oldest in the States, having been organized in 1776, with thirteen members. The first president was a minister of the gospel, as well as a practising physician. Dr. English's address contained certain suggestions which were referred to a committee of five to report with regard to their adoption in the by-laws at the next annual meeting.

Tetany.—Dr. Louis Faugères Bishop, of Morris County, reported a case of tetany, a rare disease, fewer than one hundred cases having been reported in this country. His patient still occasionally had the attacks of clonic spasms which extended from the arm, but was improving.

Election of Officers.—The following officers were elected: *President*, William Elmer; *First Vice-President*, T. J. Smith; *Second Vice-President*, D. C. English; *Third Vice-President*, C. R. Fisher; *Corresponding Secretary*, E. L. B. Godfrey; *Recording Secretary*, William Pierson; *Treasurer*, Archibald Mercer. The next meeting will be held at Asbury Park, the fourth Tuesday in June, 1896.

New Instruments.

A NEW MASTOID RETRACTOR.

By MAX THORNER, A.M., M.D.,

CINCINNATI, O.

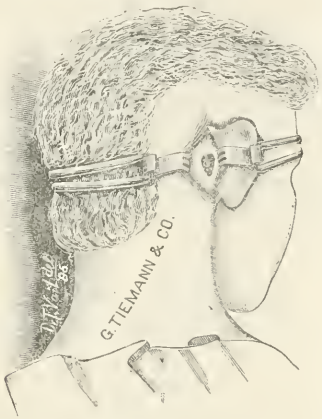
PROFESSOR OF CLINICAL LARYNGOLOGY AND OTOLOGY, CINCINNATI COLLEGE OF MEDICINE AND SURGERY (MEDICAL DEPARTMENT OF THE CINCINNATI UNIVERSITY); LARYNGOLOGIST AND AURIST TO THE CINCINNATI HOSPITAL, ETC.

During a mastoid operation the field of operation must be kept thoroughly clear by having the margins of the wound well drawn apart. After making the incision parallel to the insertion of the auricle, and stopping the hemorrhage, the bone is denuded by pushing the parts backward and forward with a raspatory. The margins of the wound are then kept separated during the whole operation by strong three- or four-pronged retractors, held by the hands of assistants. This is, however, not only very tiresome during protracted operations, but the hands, and especially the one holding the posterior retractor, are frequently in the way of the surgeon. To overcome this difficulty several devices have been invented, as, for instance, the self-retaining retractors of Barth, Zarniko, Allport, and Bishop. All of these are constructed on the principle of two retracting hooks, united at the lower extremities by cross-bars, or by screws; by which they are also separated and kept so during the operation. For some time I have been using a little device that is so exceedingly simple and has given such universal satisfaction, to me and a number of colleagues, that I think it will readily recommend itself for this and similar operations.

The instrument consists of a flat S-shaped piece of steel, about one inch and three-fourths long, and five-eighths of an inch broad. One of the extremities is shaped into a three- or four-pronged hook, while the other extremity forms a blunt, broad retractor, bent in the opposite direction. This instrument is used in the following manner:

When the bone is well denuded and the periosteum pushed aside, the prongs of one retractor are well hooked below the periosteum of the posterior margin of the wound, and the prongs of the other retractor below the parts of the anterior margin (*i.e.*, the detached auricle). Then a long strip of sterilized gauze, about an inch and a half broad, and preferably doubled, to render it stronger, is folded in its middle over the blunt end of the anterior hook, drawn across the forehead and around the head of the patient, and fastened tightly over the blunt hook of the posterior re-

tractor. Instead of the strip of gauze one may also use a long rubber ring, as was suggested to me by Dr. Vail, of this city, to whom I am also indebted for the sketch from which the cut has been made. Sometimes the amount of tissue which is to be held back by the anterior retractor is so enormous, comprising the auri-



cle and more or less infiltrated tissues deep down into the external auditory canal, that the usual anterior hook, as shown in the cut, cannot sufficiently grasp it, to embrace it well, as it were. For such cases, and their number is not small, I have had constructed, at the suggestion of Professor S. C. Ayres, a special anterior hook in which the pronged end is about one inch distant from the flat shaft. With this hook, especially if we have one somewhat (about one-fourth to three-eighths of an inch) broader, and having four instead of three prongs, we can safely hold back the auricle with any amount of infiltrated tissue.

This is the manner of procedure in which the antrum only is to be opened. In such operations, however, in which the upper and posterior walls of the auditory canal are to be removed, one may either apply both hooks in the above-described manner, or one may, as I would prefer in some cases, use only the posterior hook, after having drawn the strip of gauze around the detached auricle between the wall of the osseous and the cutaneous canal, and then back through the auditory canal proper, as has been recommended by Holmes.[1] The strip of gauze is then tied around the forehead and over the blunt hook of the posterior retractor in the above-described manner. Little changes in the application of the hooks will suggest themselves, of course, to the surgeon; sometimes, for instance, the relative position of the hooks will demand that the strip of gauze be carried across the upper lip, just below the nose, instead of across the forehead.

The advantages of this method are obvious. The margins of the wound are kept immovably separated, as the gauze can be fastened tightly or loosely. It can be removed or changed in an instant. One, and sometimes two, hands of an assistant are positively spared, and one may do with one assistant less. Neither hands of assistant nor cross-bars of instrument are in the way of the operator. This appliance does not get tired nor relaxed, as the hands of assistants sometimes do in protracted operations. The relative position of the hooks can be readily changed to suit the convenience of the surgeon. The posterior hook may also serve to hold down the flexible probe, which is introduced into the attic from the posterior funnel-shaped opening, after the antrum has been opened. The hooks are readily rendered aseptic, and the gauze is, of course, sterilized before the operation. Those who prefer a blunt retractor instead of a pronged or sharp one, may simply reverse the instrument. The slender S-shaped curve renders it easily adapted to the irregular surfaces with which we have to deal. And, finally, the instrument can be used for any other surgical operations, and is cheap on account of its simple construction.

Correspondence.

RECIPROCITY IN REGISTRATION.

To the Editor of the Medical Record.

Sir: On July 9th the State Board of Registration in Medicine of Maine met and organized; this makes about ten States which require an examination before a person is allowed to practise medicine, regardless of diplomas, and several States are contemplating the enactment of similar laws. But nothing can be done until the whole of the medical profession in a State is aroused, sinking at least for the time their petty quarrels and jealousies, and act as a unit.

To hasten the goal, let me propose a measure that at once would place practitioners of all other States at a disadvantage and thus almost force them to the adoption of similar laws. Let the State Boards of Massachusetts, Maine, Minnesota, Mississippi, New Jersey, New York, North Carolina, North Dakota, Texas (Vermont and Virginia when they create a regular State Board), and Washington, or a committee representing them, draw up a section to be added to their law, something like this: "And said Board may give a certificate of registration to any person, who has previously been registered in another State where, in the judgment of the Board, the standard of such registration is equal to the requirements in this State, upon the presentation of satisfactory proof and payment of the usual fees, etc."

You will notice, sir, that I would make it perfectly voluntary upon the board to do so or not by the use of the word "may," and yet it would undoubtedly answer every purpose.

I object to the methods of such States as Alabama, California, Connecticut, District of Columbia, Maryland, New Hampshire, Vermont, Virginia, and Wisconsin, where the examination, which is not always required, is conducted by the various medical societies, or to Arkansas, Florida, Oklahoma, and a few others where there is a board for every section of the State. There should be one central body, appointed by the governor, where the different medical sects that are worthy of recognition should be represented. Examinations should be practical and to the point—not like the examiners in pharmacy in one of the New England States, who try to elevate their profession by "sticking" the greatest amount of candidates by theoretical suppositions, and who have only succeeded in creating a new class of frauds, crammed with just such questions and answers, who for a consideration will go and be examined in almost anybody's name.

The standard should be uniform throughout all the States, a matter which a committee could easily arrange, and then, when once registered, a practitioner would be so forever.

The convenience resulting from such a law would undoubtedly swing all the other States into line, and then the formation of a National Board of Medical Examiners would be in order, whose certificate would be good everywhere.

Country Doctor.

East Eddington, Me., July 1895.

THE PRESENT STATUS OF ANTITOXIN IN LONDON.

To the Editor of the Medical Record.

Sir: Having just returned from a trip to England, and thinking the readers of the Medical Record, like myself, would be interested to learn the latest English results concerning the antitoxin method in treatment of diphtheria, is my excuse for sending you these few lines.

Knowing that in London there were several hospitals devoted exclusively to the care and treatment of infectious diseases, I took occasion to visit one of the largest, viz., the London Northwestern Fever Hospital, on purpose to find out for myself, from the physicians in charge, the results of their experience with this so-called cure for diphtheria.

I was very cordially received by the resident physician, and after stating the object of my visit, he kindly consented to furnish me all the information he had at his command, and at the same time invited me to accompany him through the various wards of the institution, which I did. The hospital itself is composed of several detached frame buildings, each of which accommodates from twenty-four to fifty patients, the aggregate capacity of the institution being four hundred beds. These frame buildings are now being rapidly displaced by more capacious modern brick and stone structures, so that the hospital is now undergoing extensive alterations. Each building was neat and clean, and furnished with comfortable beds, which were occupied with patients, for the most part children, suffering from either diphtheria or scarlet fever in their various stages.

"This," said the doctor, "is one of seven hospitals in London devoted exclusively to the treatment of infectious diseases." "How many cases of diphtheria have you here at the present time?" I asked. "About two hundred," he said. "Have you used the antitoxin in your treatment of them?" "Yes, we have been using it here since the first of the year." "What has been the result of your experience with it?" "It has proven an unfortunate failure." "How do your results compare with the other similar institutions?" "We are all agreed, with but one exception, and he is rapidly withdrawing his former premature statements in regard to its efficacy." "Do you confirm your diagnosis by making cultures?" "Yes, in every case." At this juncture a porter informed the doctor that a new case of diphtheria had just arrived. "Come," said he, "and I will show you how we receive patients at this hospital, and how we make our cultures." An opportunity was here afforded which I was very glad to take advantage of. "Do you often have mistakes in diagnosis?" I asked. "Yes," said the doctor, "we often get cases of tonsillitis for diphtheria, and measles for scarlet fever." "In cases of doubt, how do you avoid contamination?" "We have a receiving ward in which doubtful cases are kept isolated while yet under observation, until we are satisfied." "What is your rate of mortality?" "Twenty-seven per cent., which includes all cases; this could be reduced to twenty, if only the acute cases are considered." "Has this been increased or diminished since you have used the antitoxin?" "No," said he, "it has remained the same. Indeed, I believe that the antitoxin is harmful to the patients, because it produces a rash, which again increases the fever and renders the patients much more ill than they usually were before we used the remedy." "Are you still using it?" "Yes, we do not wish to discard it until we have given it a sufficient trial to satisfy the most sanguine mind, but for myself, I am now ready to brand it as a complete failure." "How is it regarded in the States?" he inquired. I replied that it was still in the scales being weighed, and that many had formed the same conclusions as himself, while others thought it was the only cure for diphtheria.

Before taking my leave I was invited to partake of the inevitable cup of tea, which is so common a part of English social life, and thus ended what I considered a very profitable afternoon's outing in London.

J. Punton, M.D.,
Professor of Nervous and Mental Diseases, University Medical College, Kansas City, Mo.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 13, 1895.

	Cases.	Deaths.
Tuberculosis	166	112
Typhoid fever	18	3
Scarlet fever	50	4
Cerebro-spinal meningitis	2	5
Measles	210	29
Diphtheria	196	19

Professor Cesare Lombroso was born in 1846, in Venice, of Hebrew parents. After being graduated in medicine he became interested in diseases of the mind, and especially in criminal anthropology, of which science he has been called, though not in strict justice, the founder. He is now Professor of Medical Jurisprudence in the University of Turin.

The Regents of the State University have voted to confer the university degree, M.D., only after one year's post-graduate study subsequent to receiving the degree of bachelor or doctor of medicine from some registered medical school, and only on candidates who have spent not less than four years' total study in accredited medical schools.

The State Medical Library.—Chancellor Upson, of the regents, has appointed Drs. Charles E. Jones, S. B. Ward, and Willis G. Tucker, of Albany, as an advisory medical library council for 1896, to recommend books to be bought and to confer with the director of the library in any matters connected with the new State medical library, which may be submitted to them.

Charing Cross Hospital, in London, is in financial straits. It is proposed to remove the hospital to Camberwell, south of the river, and to sell the valuable site on which it now stands.

The New York State Medical Law.—In a recent issue we published the full text of the codified medical laws of the State of New York as they existed before the session of the last Legislature. In order to emphasize the changes made by this latter body (and these are the *only* changes, notwithstanding misleading items published in some medical journals), we herewith append the amendments. Section 145 has been amended by Chap. 636 of the Laws of 1895, which became a law upon May 13, 1895. The amendment relates to the preliminary education requirement. The second paragraph of this section now reads as follows, the amended portion being in italics:

"The degree of bachelor or doctor of medicine shall not be conferred in this State before the candidate has filed with the institution conferring it the certificate of the regents that three years before the date of the degree he has either graduated from a registered college *or satisfactorily completed a full course in a registered academy or high school; or had a preliminary education considered and accepted by the regents as fully equivalent; or had passed regents' examinations representing for degrees conferred in 1898 one year of academic work, for degrees conferred in 1899 two years of academic work,*

and for degrees conferred in 1900 a full high school course. Students who had matriculated in a New York medical school before June 5, 1890, shall be exempt from this preliminary education requirement, provided the degree be conferred before August 1, 1895. The regents may, in their discretion, accept as the equivalent for any part of the third and fourth requirement evidence of five or more years' reputable practice, provided that such substitution be specified in the license."

Section 153, under which illegal practitioners are proceeded against, has been amended by Chap. 398 of the laws of 1895, and this amendment is of a most comprehensive character. By restoring the provisions of the former act of 1887 which gave the fines to the Medical Societies, it renders the systematic prosecution of offenders again feasible. This section now reads as follows:

"§ 153. *Penalties and their collection.*—Any person who, not being then lawfully authorized to practise medicine within this State and so registered according to law, shall practise medicine within this State without lawful registration or in violation of any provision of this article; and any person who shall buy, sell, or fraudulently obtain any medical diploma, license, record, or registration, or who shall aid or abet such buying, selling, or fraudulently obtaining, or who shall practise medicine under cover of any medical diploma, license, record, or registration illegally obtained, or signed, or issued unlawfully or under fraudulent representations or mistake of fact in a material regard, or who, after conviction of a felony, shall attempt to practise medicine, or shall so practise, and any person who shall append the letters M.D. to his or her name, or shall assume or advertise the title of doctor (or any title which shall show or tend to show that the person assuming or advertising the same is a practitioner of any of the branches of medicine) in such a manner as to convey the impression that he or she is a legal practitioner of medicine, or of any of its branches, without having legally received the medical degree, or without having received a license which constituted at the time an authority to practise medicine under the laws of this State then in force, shall be guilty of a misdemeanor, and on conviction thereof shall be punished by a fine of not more than $250, or imprisonment for six months for the first offence, and on conviction of any subsequent offence, by a fine of not more than $500 or imprisonment for not less than one year, or by both fine and imprisonment. Any person who shall practise medicine under a false or assumed name, or who shall falsely personate another practitioner of a like or different name, shall be guilty of a felony. When any prosecution under this article is made on the complaint of any incorporated medical society of the State, or any county medical society of such county entitled to representation in a State society, the fines when collected shall be paid to the society making the complaint, and any excess of the amount of fines so paid over the expense incurred by the said society in enforcing the medical laws of this State, shall be paid at the end of the year to the county treasurer."

Complete copies of the amended law can be obtained by addressing the Regents' Office, Albany, N. Y., or on application to the Secretary of the State Board of Medical Examiners, 78 West Eighty-second Street, New York City.

The Mutilation-market and the Business of Mendicancy.—Austro-Hungary is acquiring an evil pre-eminence in the manufacture of deformity and *lusus naturæ*. Some eighteen months ago we commented on the discovery made by the Croatian police of a regular mutilation-den, where boys and girls of tender years were distorted or maimed to supply the mendicancy-market—and where, by fracture or by continuous pressure between boards tightened by screws, the legs and arms and spinal columns of these poor little victims were made to assume monstrous shapes—where even the eyes were gouged out and artificial sores created—all to provide the traffickers in street-begging with "objects" wherewith to solicit the alms of the benevolent. (*The Lancet.*) The arrest and punishment of these purveyors of deformity seem, however, to have put no effective stop to the practice, for we read in a Hungarian journal that at Prague a man, Proschaska by name, was taken into custody charged with selling to the firm of Ritter & Munster, of Holstein, a number of children who, by means of specially contrived alimentations, had had their growth arrested for exposure as "Liliputians" in itinerant exhibitions. For every child so stunted and maltreated the sum of 300 florins was paid. We further read that not only were the authors of the "Liliputianizing" system brought to justice, but also the unnatural parents who consented to its being applied to their offspring, and who received money for doing so. This is, of course, quite commendable on the part of the law; but we fear its heaviest punishment will have small deterrent force so long as the public does not co-operate in suppressing the "business of mendicancy." Indiscriminate alms-giving lies at the root of the whole evil. Rather than take the trouble to ascertain where relief can most worthily and effectively be bestowed, the so-called "benevolent" man will lavish his small change on every beggar who crosses his path, thereby creating half-a-dozen similar beggars for every one he subsidizes, and depriving the really well-organized charities of the funds of which they are sorely in need. One of the most large-hearted economists of his generation, Archbishop Whately, congratulated himself at the close of his life that he never gave a penny to a beggar, but that the money withheld from such objects had been profitably bestowed on the institutions, medical and other, where succor was vouchsafed only to the deserving. If the public acted with equal wisdom and stiffened its back against the professional mendicant, while relaxing its purse-strings in support of well-accredited charities, an end would speedily be made of the "business of beggary," with all its concomitants of "mutilation-dens" and "Liliputian farms," and *lusus naturæ* manufactured and supplied to order. We hope the subject will be adequately discussed at the International Congress for the Protection of Infancy, which will meet next July at Bordeaux.

Onychophagia.—M. Bertillon, whose anthropometric system of identifying criminals has made his name so well known in connection with the outward and visible signs of inward abnormality, now tells us that biting the nails—or, to give it its scientific name, "onychophagia"—is a sign of degeneracy. It is an uncleanly habit which, in some people, takes the place of that "whittling" in which some New Englanders find relief for their superfluous energies. Long ago Dr. O. W. Holmes, in his "Autocrat" pointed out that punning might be an early symptom of insanity, and in that opinion we are inclined to agree with him, at least if the vice is habitual and suggestive of irresistible impulse; but it is hard that one should be convicted of degeneracy on the strength of ragged nails. What about other unconscious or semi-unconscious acts? Is a well-known reformer to be called degenerate because he constantly chews tobacco (when he is not drinking tea)? or the great masses of humanity who indulge in chewing-gum? It is dangerous to have a trick of any kind in these days when the disciples of Lombroso are among us "takin' notes," or when rubbing the nose or cracking the fingers may, to the seeing eye, be as fraught with mystic meaning as our Police Commissioners' midnight ventures.

Chloroform in Typhoid.—Dr. Quill, of the British Medical Staff in India, has treated a large number of cases of typhoid fever with chloroform and carbolic acid internally, and claims to have had excellent results.

PREGNANCY ASSOCIATED WITH DIABETES.[1]

By EDWARD L. PARTRIDGE, M.D.,

CONSULTING PHYSICIAN, NEW YORK HOSPITAL; CONSULTING OBSTETRICIAN, NEW YORK INFANT ASYLUM.

In a consideration of the subject of this paper, it will be impossible to do more than present the experience of a few observers of the association of the two conditions of diabetes and pregnancy. But little has been written on the subject, and the opinions of the writers have been reached on comparatively little experience. The presentation of the subject by those who have written has been forcible, however, and there exists, in the minds of those who are acquainted with the subject through this literature, an impression that very great danger attends the association of glucose in the urine and pregnancy. On more than one occasion the question has been anxiously raised as to the course to be pursued when these conditions co-exist, and a brief review of our knowledge on the subject may be proper and interesting, even if devoid of much result of a practical nature. By result of a practical character, I refer to the formulation of rules of guidance in reaching prognosis, and decision as to the proper treatment, especially in regard to the interruption of the pregnancy. That we would welcome conclusions which we could feel to be well-founded, we clearly realize. Have deductions of this nature been reached?

Glucose in the urine of a pregnant woman may appear for a single examination, or be occasionally present and, to a slight degree, constituting a glycosuria within the limit of what may be physiological. We may meet with pregnancy occurring in a woman who has the disease diabetes, or diabetes may develop during pregnancy, continuing thereafter; or, finally, we meet with instances in which diabetes develops during pregnancy, lasting through a considerable part, or the whole of gestation, and disappearing to recur in succeeding pregnancies, the instances of the latter class constituting what might be called, perhaps, "puerperal diabetes."

Glycosuria during gestation has attracted the attention of all who have occasion to make urinary analyses of pregnant women. By glycosuria we understand the amount of glucose to be small, and the condition need never be confounded with diabetes. Inasmuch as urinary examinations do not require frequent repetition during pregnancy, and as the majority of practitioners do not look for glucose, and furthermore, as glycosuria may exhibit itself on occasional days, or in certain parts of the day only, it is probable that this modification of the blood and urine may be much more frequent than it is reported to be. It is in the latter months of pregnancy that it is most commonly observed, and it is then that the more profound disturbances of the economy, through the influence of pregnancy, are present. One theory of the production of glycosuria relates to the activity of the mammary glands at this time, with a disposition to the production of milk sugar, which by its presence in the blood, or resorption, makes its appearance in the urine.

[1] Read at a meeting of the Practitioners' Society of New York, May 3, 1895.

However this may be, it is true that with the activity of the mammary glands attending the establishment of lactation after childbirth, glycosuria is quite common. By the early investigations of Blot, later by Tarnier, and at the Simpson Memorial Hospital, physiological glycosuria has been shown to be very common. Berberoff notes that of twenty-five women just confined, thirteen exhibited glycosuria. The theory of relation between glycosuria and breast activity has had adherents so devoted, that the proposition has been offered to include, in the critical examination of women for wet-nurses, the investigation of the urine, and to regard the presence of sugar as a favorable indication.

Passing from this part of our subject to a consideration of diabetes as a disease, in its relation to pregnancy, we find in the important paper by Mathews Duncan much of serious import. He classes diabetes with nephritis and scarlatina, and ascribes to it—as we would to the others—especial malignity when associated with pregnancy, parturiency, or the lying-in period. He remarks "that cases of the kind are not sufficiently numerous to justify any statistical argument based on the number of the occurrences."

Fry takes a very grave view of the dangers of the complication, and in his review of Duncan's cases, it appears to me, has with some effort made them fit his theories. He would never permit a woman with diabetes to marry, and questions the propriety of marriage where there is a "strong hereditary predisposition to diabetes." Regarding obstetrical treatment by induction of labor, he says that there may be mild cases of diabetes, when there is reason to think that pregnancy will terminate naturally, in which interference is not justifiable, yet adds that "the difficult point to decide is not as to the advisability of inducing premature labor, but as to when it shall be done."

Barnes believes that induction of labor would be of doubtful value in these cases feeling that by the time indications for its adoption are reached, a perilous situation will have rapidly supervened, and results would not be modified by such a course. We can see that the explanation of the record of so few cases lies in part in the fact that general statistics show women to be less disposed to diabetes in the early, or child-bearing, period of life than men; and furthermore, when attacked between the ages of twenty and twenty-five, they are often subjects of amenorrhœa, or the general health is so deteriorated that marriage and pregnancy are less liable to occur.

Diabetes, in its unfavorable aspect during pregnancy or the lying-in state, presents certain cases of sudden death in coma or collapse. It has been thought also that, following a safe delivery, there is more rapid progress of the disease when it has been known to have existed during pregnancy. Duncan finds one case, however, which shows that diabetes may not return in pregnancy occurring after its cure. A fatal case reported by Fry, in 1891, occurred in the second pregnancy of the patient, diabetes developing at the fifth month. Death of the fœtus at the seventh month was followed by premature labor and the death of the mother on the fifth day. Minot, in 1888, reports a case of a woman of twenty known to have had diabetes for more than six months, who when about four and a half months advanced in pregnancy became suddenly comatose, and died in thirty-six hours. She was of

"nervous temperament; one grandfather died of spinal disease and diabetes. Her father died of tubercle of the spinal cord."

A case seen by me in the practice of Dr. Thomas T. Gaunt has the following history: Aged twenty, first pregnancy. At three months urine was normal. Second examination, at four months, showed one per cent. of glucose. Symptoms which were noted from this time to the end of fifth month—when the case was seen by me—were sore mouth, salivation, vomiting, and indigestion, loss of flesh, and prostration. She had been in bed several weeks, during which she had been on strict diet, notwithstanding which sugar had steadily increased to two and a half per cent. She was passing ninety to one hundred ounces of urine. She continued anæmic, had insomnia, and became extremely nervous, vomiting several times a day. There was present a trace of albumin, but no casts. At six months sugar reached highest point, viz., three per cent., a trace of albumin continuing, and her general condition being not essentially changed. On a somewhat more liberal diet, which her general condition demanded, sugar did not increase, and she improved a little, being up and about. At seventh month she had improved so that she could walk about and go out of doors, sugar decreasing, until at eighth month there was a trace only, urine being normal in amount. She left the city, and about this time had more marked albuminuria, with diminished urea and hyaline and granular casts. The further history, as reported, was continuance of trace of sugar, albuminuria which did not call for induced labor, confinement at term with child which lives, having been nursed by mother. One month after confinement, now two years ago, and thereafter, sugar was not present in the urine. From my investigation of current medical literature, I do not find other cases of diabetes and pregnancy reported. Such histories are likely to appear as notes of isolated cases, and a very full search might disclose more, but my impression is that these would be few in number.

It is probable that fatal cases would be reported most commonly, possessing, as they would, the most striking features. It is easy to believe that many cases, not fatal, might fail to attract attention, for in those reported by Duncan it happened, more than once, that the puzzling and alarming conditions of coma and collapse led to the investigation which disclosed the true state of affairs. When called to the case seen by me in consultation, I advised against induction of labor, feeling that this step, which would have sacrificed a life, was not justified upon any opinion founded on what I regarded as an incomplete literature of the subject, and because it appeared to me that the patient was reduced in health by other influences than diabetes. Her salivation and continued reflex digestive disturbances were sufficient to account for anæmia, loss of flesh, and acceleration of pulse.

While all urinary examinations during pregnancy should include tests for glucose—and but little additional labor attends this—special and repeated examinations should be made on the appearance of an unfavorable general condition of the patient. Highly suggestive symptoms would be thirst, dry mouth, succession of boils, polyuria, and so characteristic are these that, when present, their cause, if diabetes, would rarely escape notice. The class of cases most treacherous would be that in which obscure indications of ill-health were present, as loss of flesh, circulatory and digestive disturbances, respiratory effort, or debility. An easy and too frequent explanation for such deteriorated health during pregnancy, often as satisfactory and convincing to physician as to patient, is in the condition of pregnancy itself, which is generally looked upon as capable of producing every variety of deviation from the health standard. Herein lies a snare to be avoided by careful urinary investigation.

We have in all a collection of 25 cases of pregnancy associated with diabetes, 22 collected by Duncan (these reported by eleven different observers), 1 by Fry, 1 by Minot, and 1 by the writer, which are open to examination. These histories are fragmentary in some instances; therefore, while exact figures cannot be given as deductions, yet the accuracy of certain general statements may be asserted. The total number of twenty-five is about equally made up by the two classes, viz., women already having diabetes who became pregnant, and those acquiring diabetes during pregnancy. Among the cases of diabetes developing in the course of pregnancy, recovery took place in about three-fourths, with, however, an exhibition of a tendency to recurrence in subsequent pregnancy.

In the class in which pregnancy occurred in women already subjects of diabetes, safety through delivery and the lying-in period was apparent in about two-thirds of the cases. In most of this class ultimate history is not known, but for months at least, and in most instances for years, these women lived, and the condition of diabetes is not shown to have been influenced in either way through the intervention of pregnancy and parturition. It should be borne in mind that age has an important bearing upon prognosis in diabetes, and that between twenty-five and forty-five we encounter the greater number of severe cases, and those most prone to grave results. This is also the child-bearing period. All of the twenty-five cases reported occurred between the ages of twenty and thirty-eight, and all but three were in multiparæ. Fatal coma or collapse in diabetes has been observed to follow unusual bodily or mental exertion. Labor, certainly, is a severe tax on the physical system, a great strain to the nervous organization, and we can understand why the fatal complication, from which death may occur, should arise. Yet life presents many other adverse and trying situations beside parturition, and that these, unassociated with child-bearing, give us recognized deaths from collapse in those with diabetes is well known. Is it not pertinent to ask whether deaths associated with pregnancy can be said to arise altogether because of pregnancy? Again, in the event of death a year or more after delivery, can we properly say that a given patient would have lived longer without child-bearing?

Death of the fœtus is noticed in about one-half of the cases. Premature delivery is observed in a large proportion of the reported cases, but it is the presence of the dead fœtus which causes labor before term rather than the direct influence of diabetes. Hydramnios and excessive fœtal development are not rare, and even sugar in the liquor amnii has been noted. This seems to indicate that the products of gestation appropriate part of the water and of the sugar, despite the fact that marked elimination of both on the part of the mother is taking place.

In the instances of diabetes acquired during pregnancy, glucose in a marked degree was discovered "early in pregnancy" in three cases; "before middle of pregnancy" in one; "at four months" in one; "at four and one-half months" in two; "at five months" in two; "at eight months" in two; "at parturition" in one; showing that diabetes as a disease existed before the middle of pregnancy most commonly, and in three cases only the discovery was made after the fifth month. The histories of these three subjects do not show, however, that previous tests for glucose had been made.

In the twenty-five confinements there were six deaths in coma or collapse, closely related to labor as to time. One of these deaths took place in a woman who had diabetes before gestation, while five were in patients who acquired the disease during pregnancy. The fatal result occurred in one case at five and one-half months; in one at six months; in one at six and one-half months; in two at seven months; and in one at nine months.

It is evident that diabetes, as a grave affection, usu-

ally demands consideration before viability of the child, and the importance of tests for glucose in the early months of pregnancy is emphasized.

Coming now to a brief regard of the question of the propriety of artificial interruption of pregnancy when associated with diabetes, in the light of present knowledge we cannot see our way clearly, certainly not to the sacrifice of infant life in every instance coming under our notice. Duncan, a pioneer in the study of the subject, decided that he "could not lay down any special rules of treatment." In instances, comparatively few, when the question of treatment arises after fœtal viability, we may safely say that, by getting the patient into the best possible condition through diet and perhaps drugs, by which symptoms pertaining to the nervous system are quieted, induction of labor should be adopted. The advantage of this procedure (excited consideration of the subject by the patient not having been permitted previously) lies in the shorter time required than when spontaneous labor is allowed, and in the judicious use of chloral or other anodyne in the early part of labor, and chloroform and instrumental aid early in the second stage. It has been noted, however, that such selected cases have been rare—and in but one known instance has induction of labor been resorted to, in which case the patient was in a dying condition at the time of the operation.

Inasmuch as instances of the appearance of diabetes early in pregnancy, before the viable age of the fœtus, are more common than those of late appearance, the question of production of abortion is one which has to be met, and proves to be a complex one. We have no experience with this form of treatment to aid us in settling it, and it would seem that the knowledge of, and experience with, the disease diabetes can contribute to an *à priori* opinion as much as, if not more than, an obstetrical consideration of the subject. The most profitable line of study might be, perhaps, that which will determine what history and existing symptoms of diabetes afford a serious presentment of the disease, one which apart from pregnancy would constitute a grave case, such an one as would demand interference if associated with pregnancy. May it not be true that family history and temperament, particularly the latter, are matters of importance? The nervous organization is that which most keenly feels and is influenced by physical or mental strain such as may attend pregnancy and parturition. Do duration of disease, amount of glucose considering both percentage and quantity of urine, afford indications for interruption of pregnancy? In a case of long history, with attacks of threatened coma, or collapse, the indication would seem most plain. Absence of knee-jerk, and pains and disability of lower extremities indicating neuritis or spinal cord irritation, furunculosis, and emaciation, when other causes than diabetes can be excluded, must each be given defined position in relation to gravity of diabetes.

Unless we have a group of symptoms which betoken a very critical situation, we may help settle our question—while at the same time we benefit our patient—by resorting to dietetic and other treatment, from which we rarely fail to obtain some improvement, before more radical procedure. We have to admit that the least nervous excitement and strain, and less physical disturbance, would attend interruption of pregnancy in the early months.

Thus we seem compelled to the conclusion that each case must be considered by itself, as to its exigencies, as we have no special rules of guidance.

The value of infant life and the right to its sacrifice must be a part of such a question as this, and here we ever meet with much variance of opinion. The social economist, the physician studying this subject in the abstract, the physician in close relation to his patient, and the layman closely related to the patient, has each his own point of view.

EXPERIMENTAL PSYCHOLOGY

By E. B. TITCHENER, A.M., PH.D., F.Z.S.,

ASSISTANT PROFESSOR OF PSYCHOLOGY AND DIRECTOR OF THE PSYCHOLOGICAL LABORATORY AT CORNELL UNIVERSITY, ITHACA, N. Y.; MEMBER OF THE NEUROLOGICAL SOCIETY OF LONDON, AND OF THE AMERICAN PSYCHOLOGICAL ASSOCIATION.

In the list of the instructors at any of the principal American universities will be found some name with the title "Professor of Experimental Psychology," or "Director of the Psychological Laboratory." Those are curious titles. Fifty years ago they would have been as unintelligible and impossible as the titles "Professor of Experimental Logic" or "Director of the Theological Laboratory" would be to-day. The nineteenth century has seen the doing of many wonderful things: but surely nothing is quite so strange or wonderful as this—the construction of laboratories in which the material experimented on is the human mind.

For it is mind that the psychologist is busied with. Psychology is the science of mind. Everyone knows what mind means; or, at least, everyone uses the word quite commonly in conversation. People say: "I cannot make up my mind." It is that which they cannot make up that the psychologist experiments upon. Or they say: "I have half a mind to do it." Or again, if they are in doubt about something, and ask a friend for advice, they may be told: "Look into your own mind, and do what it tells you." And we are accustomed to characterize a person as strong-minded or weak-minded, as possessing a logical mind, or a quick mind, or an acute mind, and so on. Mind, in all these senses, is the subject of the psychologist's study.

But that, of course, is mind in the rough. One cannot begin to work upon mind, in that sense, without further preparation. Let me give an illustration. Physics deals with the properties of matter—of the bodies of the world outside us. And the physical laboratory is fitted up in a way that enables the student to experiment upon natural bodies—liquids and solids and gases. But when he enters a physical laboratory he does not find there a collection of natural bodies. He finds a number of special instruments—inclined planes, and pulleys, and wedges, and pumps, and so forth. It is by their aid that he is introduced to the study of natural bodies; and his study would not be scientific if he dispensed with them. So with physiology. In the physiological laboratory he is taught to examine the functions of the various animal organs: the uses of the heart, and the muscles, and the nerves. But when he enters the laboratory, he does not find a flock of sheep waiting to be worked upon. He finds, again, a collection of special, technical instruments; and he works with a single bit of muscle, or a single strand of nerve, by the aid of those instruments. Just the same rules obtain in psychology. When the student comes into the laboratory, he is not set to work upon mind as a whole; but at some particular little bit of mind, some special mental process. That is the technical phrase.

But how does one get to these "bits" of mind? How is this cutting-up, which seems to be a necessary preliminary to scientific work upon mental phenomena, accomplished? Why, that is not so very difficult. One only has to go to language, and ask it for help, and the thing is done. Language is fossil mind. When we talk, we do so in order to give expression to something that is in our mind. Words are symbols, standing for different bits of mind: and we have only to go and quarry among these symbols to dig out any number of separate fragments, which we can then set to work upon in the laboratory. Language distinguishes one set of mental states as emotions. Such are anger, fear, hope. It distinguishes others as feelings: pleasures and pains. It distinguishes others as sensations: such would be blue, hot, sweet, heavy. It distinguishes

others as desires, thoughts, instincts, ideas, and so on. So that mind, with which we started out as a whole, is split up by an appeal to langnage into a large number of separate mental states or mental processes. To the psychologist, mind is simply the sum total of all those mental states that language has marked off—thoughts, feelings, desires, perceptions, wishes, moods, sentiments, and all the rest. Those states constitute the material of his investigation.

Now, it is a rule of scientific inquiry to begin with the simple, and not go on to deal with the compound till we have learned all that we can learn of that. Begin with the easy, and then later proceed to the difficult. That is done in chemistry; we begin with the elements —oxygen, and hydrogen, and the like. It is done in biology; we start out with the most rudimentary animals—those that consist of only a single cell—and gradually take more difficult forms of life, till we come last of all to the most complex form that there is—man. Psychology must follow the same rule. We must begin with very simple states of mind, and travel by slow degrees from them to the more complex and difficult. And a little reflection shows us that the most simple mental states that we experience are our sensations. The emotion of anger is plainly complex: it contains the idea of the person who has made one angry; the idea of the act of his, at which one is angry; the idea of what his action should have been, of what he ought to have done, if one was not to be angry; it contains a sense of personal injury; there is an uncomfortable feeling in it, a feeling of discomfort and uneasiness: and there is contained in it, also, the wish to be oneself again, to be rid of one's uncomfortableness. We cannot possibly, then, begin to study mind by way of emotion. An idea, again, is a compound state. My idea of a house contains many sensations of color; many perceptions of form and outline; as well as a feeling of approval or disapproval of its beauty or ugliness. But the sensation is something different. We cannot split that up into other states. The sensation of blue: what can be simpler than that? Blueness cannot be resolved into so many ideas and feelings; it is just itself, and we cannot go behind it. So the sensation of sweet. You cannot say that it is composed of any other states; it is not a mixed state of mind, it is an ultimate and irreducible experience. So the sensation of heaviness, of pressure on the skin; or the fragrance of a rose, the sensation of smell; they are last things of mind, states at which inquiry stops short, beyond which analysis cannot go.

It will now not be surprising if I say that, when the student goes to work in a psychological laboratory, the first thing that he is set to study is sensation. He is put through a drill-course in sensation, before he is allowed to take in hand the higher mental states, like emotion or memory or attention. At the same time, there may be some hesitation in accepting the statement that sensation is a matter for the psychologist to investigate. Does not the study of sensation, it may be asked, belong by rights to the physiologist? Do we not find discussions of sensation in every physiological text-book? Cannot psychology accept the results of physiological research, instead of starting fresh on her own account? Those are all fair questions. But I think that I can show by a very simple illustration that there is work for the psychologist here, and that he is not trespassing on the physiologist's domain when he undertakes it.

For us to experience a sensation of any kind, it is necessary that a particular bodily organ be thrown into activity. We can only see, if our eye is in activity: we can only hear, when our ear is active: we can only taste if some sort of impression from outside affects the tongue. Now, these organs of sense are machines or instruments, just like the physical machines and instruments that we have around us to assist us in our ordinary employments. Suppose we compare the ear for instance, to such an instrument, we will say a piano. A piano is a single instrument, but it is made up of a large number of separate parts. There are so many pieces of ivory of a certain shape; so many pieces of wood of a certain shape; so many pieces of wire of certain lengths and thicknesses; so many pieces of felt of certain forms and thicknesses. One way, then, of describing the piano would be to enumerate all these various parts, giving exact details as to blemishes or excellences. It would be a long and wearisome way; but it is a distinctly possible way. But now all these parts of the piano, which we will suppose to have been described, are, in the instrument itself, grouped together, held together in systems, by hinges and levers and screws. One system would consist of the *c*-string, with the felt-headed hammer that strikes it, the lever connecting the hammer with the ivory note, this note *c* on the keyboard itself, and the part of the damper that works upon the *c*-string. There are some eighty-five of these systems in the instrument. Plainly, another way of describing the piano would be to give an account of one of these systems; to say that it consists of a number of pieces put together for a particular purpose, and to state what this purpose is. Instead of giving details as to the defects or excellences of the various bits of wood or metal or ivory, the describer would state the defects of the system, or its advantages, with reference to the work which it had to do. He would say that the systems in the bass did not work, because the wires were badly strung; that particular notes could not be sounded, because the hinges were jammed, and so on. This description would be different altogether from the first one, but it would be a good description from a certain point of view. And now, lastly, a third description might be given in terms of the tones which can be got from the piano. One might say that it was mellow in tone, or that its tone was metallic; one might say that the bass chords were richer than the treble; or, going into details, one might calculate out how many tonal combinations it was capable of producing, or ask how its tone differs from the tone of the organ or the trumpet, which are also musical instruments. Apply all that to the ear. The same three stand-points are possible. The man who enumerates and describes all the separate parts of the ear is the anatomist. The man who describes the ear in regard to its purpose or function is the physiologist. He will tell us what all the anatomical portions of the ear are for, and whether they are well or ill adapted to their purpose; he will tell us how the ear works, when a vibration of the air outside of it throws it into activity. The man who pays attention to the sensations of hearing, who asks how many different tones the ear can appreciate, how all these various tonal sensations combine in the mind when they are given together, what it is that marks off in the mind the note of a trumpet from the note of a clarionette, how it is that some tonal sensations and combinations of them are pleasant, and some unpleasant—that man is the psychologist. The anatomist finds that there are enough pieces in the ear to allow of the construction of systems for 11,000 tones. The physiologist finds that there are 11,000 working systems for tones, if the ear is normal. The psychologist finds that we can have 11,000 distinct sensations of hearing. But music uses less than 100 of those 11,000. There is a further problem for the psychologist. Why is it that music does not employ more tones? Why, of all the possible tones, does she employ just these that are given by the various musical instruments, and not another set of tones altogether? These questions can only be answered by an examination of the mutual relations existing between tonal sensations in the mind. In a word, after the spheres of anatomy and physiology have been travelled through and left behind, there is another domain before us, demanding exploration, the territory of psychology.

That, I hope, is a satisfactory answer to the objection that I imagined to be made just now, the objection that the study of sensation belongs to physiology, and not to psychology. It is plain that the student can be put through the drill-course that I mentioned in a psychological laboratory, and be kept strictly within the bounds of psychological investigation. And now, enough having been said by way of introduction, I can go on to tell something of what a psychological laboratory actually looks like, and of the problems that are worked at there.

If I were showing a visitor my own laboratory I should take him first of all into the acoustic-room. In that room he would find all manner of sound-, or rather tone-, producing instruments. He would find organ-pipes; tiny whistles, carefully constructed to tell how many vibrations in the second the air-wave that strikes the ear is making; he would find a piano; strings, and bows to sound them with; he would find chests containing metal tongues of different lengths, which can be set vibrating by a draught of air; blocks of wood which give different notes when one strikes them; steel rods which give deep bass tones when one sets them swinging; and above all he would find tuning-forks: tuning-forks on resonance boxes, that boom all through the room when they are struck, and little hand tuning-forks, that will give the full chromatic scale, but are so faint that they must be held close up to the ear to get the tone; tuning-forks whose tones are thousands of vibrations in the second apart from one another, and series of forks whose tones differ from each other only by a fraction of a vibration; tuning-forks that are as tall as he is himself, and tuning-forks whose prongs are so short that they are hardly anything more than little knobs of metal side by side at the top of the handle. All these instruments we employ to answer the questions which I spoke of a moment ago: the range of hearing sensations (anything between the rates of 16 and of 50,000 vibrations in the second can be heard); the capacity of the ear to discriminate between very similar tones; the manner in which simultaneous tones blend and combine in the mind to form single ideas; the laws of the musical scale; the mental process by which we hear an organ tone as different from the tone of a flute, and so on. All that would form a part of the student's drill-course in sensation. Then I should take my visitor into the optical-room. There is a quite similar collection of instruments. We have instruments for determining of how many sensations of light and color the eye is capable; there are about 40,000 of them. Others show how visual sensations are modified by the presence of other sensations in the mind: these are the phenomena of color-harmony and color-contrast. Others show how the form and size of visual sensations are affected by the various possible eye-movements. Others again measure the eye's power of discriminating between sizes and forms that are very nearly alike. Others demonstrate how long the sensation lasts, and what its nature is, after the physical stimulus has ceased to work. Yet others show us how the sensations from the two eyes blend together harmoniously to give us a single perception, and so on. All these instruments and their uses have to be learned by the student of psychology. Then in another room we have apparatus for the investigation of the other senses. Thus for the sense of touch there is an instrument that carries a point over the skin at a constant rapidity, and in a constant direction. The point is moved up-hill and down-dale, over the surface of the skin, at a perfectly even rate; and the place that you have worked over to-day you can work over again to-morrow, without deviating by a hair's breadth from the old path. Then there are other instruments for giving simultaneous impressions of equal heaviness, on the skin. By their aid one can discover how good the skin is at estimating distances in space. You put down two points, an inch apart, with equal pressure: and after a moment's interval two different points, which are one and an eighth inch apart, and you ask whether the skin feels that one of the distances is longer than the other, or if it is incapable of discrimination of such a small difference. Then again there are delicately graduated series of weights, by the help of which we can tell how fine the discrimination of our muscles and tendons is, they being the organs involved, of course, when weights are lifted. And there are plenty of others. Lastly, we have apparatus for the examination of smell and taste and the temperature sense, although these are not by any means so elaborate or so perfect as those that I have mentioned hitherto. All of them must be mastered and tested by the student.

The first thing, then, that the beginner in experimental psychology has to do, is to get a thorough knowledge of the sensations, and of the laws which govern their appearance, and the mode of their combination in mind. There is another branch of training which is not quite so elementary, but equally important. That is, training in what are called reaction-experiments. I must say a few words about them.

The typical reaction-experiment is very simple. The experimentee sits, we will say, in a dark room. Suddenly, a light flashes out from the darkness. As soon as the observer has seen the light, he makes some movement; the movement is his response to the light, and has been agreed upon beforehand between himself and the experimenter. That is all—the execution of a definite movement, in answer to a definite sense-impression. But the way in which the experiment is controlled makes it valuable.

The instruments are always so arranged that the time elapsing between the giving of the impression and the performance of the movement in response to it can be measured. At the moment that the impression is given an electric clock is set going; and at the moment that the movement is made the clock is stopped. The apparatus that gives the flash closes an electric circuit; the movement that answers to it breaks the connection of an electric key. The clock goes just for the few hundredths of a second between closing and breaking. Thousands—tens of thousands—of these time-records have been taken, and we now know within a few thousandths of a second exactly how long it ought to take a man to execute a movement in answer to a flash of light, a sharp snapping sound, or the prick of an electric current sent into his skin.

The time values are important in themselves to one who knows how to interpret them. But for the beginner in psychological work they are of more importance in another direction, both in themselves and for what they tell his instructor about him. For instance, if a man's reaction-time is too slow, and remains too slow in spite of practice, it is of no use to go any further with him in experiments upon the will or the attention; and so if the times are consistently too short, or if they are persistently irregular. Again, the instructor knows that the length of the reaction-time will differ, according as the subject directs his attention principally to the sense-impression or to the movement he is to carry out in response to it. He will therefore say: "In this set of experiments, attend as closely as you can to the flash, and never mind the movement." And at another time: "Attend to the movement, and do not trouble so much about the flash." If the experimentee is a person accustomed to control and examine his mind, if he is the stuff that psychologists are made of, he will be able to direct his attention as he is told; and the instructor can read off from the electric clock that the attention is going in this direction in this experiment, and in that direction in that. In this way he can sift out the attentive students from the scatter-brained, almost at a glance; and that is no small advantage. On the other side, the student is benefited by reaction-experiments in a way in which he cannot be by experiments on sensation—he has to learn to control his mind very accurately, to

keep a tight rein over his attention, to concentrate himself and not follow up a distraction, to watch closely that he fulfil exactly the conditions of the experiment. No small advantage this to the student. For the reaction is the type of all action. In every-day life one has an idea and acts on it. In the laboratory one has a simple sensation and acts in a definite way upon that. The one case is exact, the other inexact; that is all the difference. To act resolutely, unhesitatingly, without flurry or precipitation, that is what is learnt from reaction-experiments. And that is the second part of psychological drill-work.

It is obvious, now, what the contents of another room in the laboratory will be. There will be instruments which give a sense-impression, at the same time that they close an electric circuit. We have a large pendulum which sends a flash of light in this way; a set of electric hammers for giving sharp, short taps of sound; and instruments for sending a momentary electric current into the skin. Then we have all kinds of apparatus to regulate the movement made in answer to the impression; the reactor may answer by just lifting his finger off an ordinary telegraph key, or by opening out his thumb and finger, or by opening his lips, or by speaking a word into a funnel. And, thirdly, there are the electric clocks themselves, with instruments to test their accuracy, and other instruments to test the accuracy of those testing instruments. All this has to be understood theoretically, and handled practically, by the student who comes to work in the laboratory.

Those are the two sides of elementary laboratory work. The sensation-drill teaches the beginner what it is necessary for him to know about the elementary processes of the mind, the very simplest bits of mind that we can reach; and at the same time gives him practice in handling instruments of precision. The reaction-drill teaches him to get control of his mind, to make it do just what he wants it to do at the moment; it makes him steady and patient and reliable. When the student has got as far as this, he may be allowed to begin experimental psychology.

For so far we have hardly crossed the threshold into the science proper. One would hardly say that the student who had worked through an elementary arithmetic had "begun mathematics;" you do not really begin mathematics till you get to somewhere about the calculus. And it is the same here. The student of whom we have been talking has now obtained a base of operations, from which to attack experimental psychology; but nothing more. We will suppose that he wishes to continue. What will he have to do?

Well! in general terms it is easy to answer that question. His work will be the experimental examination of the more complex mental states. He may take up any kind of problem that he likes: his material may be ideas, and their laws; or feelings, and theirs; or memory; or imagination; or attention; or what not. What department of inquiry he chooses will depend upon his particular tastes, and on what has interested him in the course of his reading and drill-work. There are a certain number of classical experiments upon these higher mental processes which it is the instructor's duty to see that he repeats and understands; but, apart from them, he will be allowed to choose for himself what side of mind he devotes himself to especially. It may be thought that it is a little early for this freedom of choice, the drill-course being only just concluded. But this must be remembered: If our particular student is to get others to serve as his experimental subjects he must pay them back in kind, by letting them experiment on him. And as he will himself require some half-dozen assistants in his own work, he will devote half-a-dozen hours a week of his own time to other investigations. So that there is no fear of his becoming prematurely one-sided.

What are these special problems like? We will take he subjects that I named just now. First of all, ideas. One may work experimentally upon the problems of the association of ideas, as it is called. If I were to write up the word "pin" before a class upon a blackboard, and to ask my audience to read that word, and then to write down the first word that came up in their minds after they had read it, three-fourths of the women would write down "cushion," and three-fourths of the men "needle." Those words are very frequently connected or "associated" in their minds. Now, there are several laws or rules of this association of ideas, and they can only be got at by experiment. Secondly, I mentioned feelings. It is a matter of ordinary experience that we find certain impressions pleasant, and certain others unpleasant. We can make that fact the material of experiment. We can take a long series of colors, for instance, and expose them one by one, asking the experimentee to select those which are pleasant and those which are unpleasant. Or we can take a series of forms—rectangles, or ovals, or crosses—and expose them to the observer, and let him choose out the proportions that he finds most pleasing in them. In this way we shall discover whether there is one universal law—whether all of us like the same forms and colors, and dislike the same, or whether there are differences between one individual and another. That is what is called the serial method of experimenting upon the feelings. Another method, which is only just now beginning to be developed, is termed the expressive method. You present objects to the observer, or you place him in certain conditions, and you register the phenomena of expression, which indicate whether he is pleased or displeased with things. Thirdly, I spoke of memory. We can make a person learn by heart a series of words, or of meaningless syllables, and call upon him to repeat them at some future time. The memorizing must be done by a definite number of repetitions; and the time of recall must be definitely fixed. Then we can tell what the laws of memory and forgetfulness are; what kind of words we remember best, and what kind worst; and by varying our experiments, we can find out why these laws hold. As regards imagination. We can place the observer in a dark room, and tell him that at a particular place upon the black surface before him he will presently see a faint light. We ask him to state when he sees the light, and to describe its form and color. Many a student, sitting in this way in the dark chamber, has seen lights which did not exist outside of his own imagination. And these phenomena, curious as they are, have their laws, like all the rest. Then, lastly, as to attention. We can inquire how many ideas the mind can attend to at one time; or how long it can attend without relaxation to a single idea; or what is the difference between the idea to which we attend, and the idea to which we are inattentive; and what happens to an idea when we distract the attention from it; and so forth.

All these problems require special apparatus; and all this apparatus will be found in a well-equipped psychological laboratory. We have particular instruments to study memory, under all its aspects; and particular instruments to study the attention. As for imagination: not only have we at Cornell an ordinary dark chamber, like the dark chambers that the photographers use, but within that we have built another smaller chamber, the darkness of which is such as may be felt. Until one has been in a chamber like it, one does not know what real darkness is; and when one does go in, one does not wonder that the unfortunate observer placed there should see in his mind's eye very strange things indeed.

That is the kind of work that the experimental psychologist is engaged upon. But as the concrete is always more interesting than the general, I will end by saying a word or two about the three principal pieces of work that we have done or are doing at Cornell. The first is this: We all know that the skin appreciates space; and we know that the eye appreciates space

Now, the two organs do not agree. Think how large the cavity of a hollow tooth feels to the tongue, and how small it looks. Think how large a blemish on the face feels to the finger, and how small it looks. There is a problem. In cases where both organs are involved in a space-judgment, how are the two verdicts of size reconciled? We hope that we have solved that problem; at least, in part. The second is this: When we are reading the page of a book, we overlook misprints. If a letter is wrong, we still read it as right. Within what limits is this right reading of a wrong group of letters possible? Do we pay most attention to the shape of a word, neglecting the letters? Or do we look most at the first syllable, and overlook the rest? That is another problem at which we are working; and we have good hope of settling the questions involved. And the third is this: If we are doing anything under difficulties, if we are forcing our minds upon it in face of distractions, we oftentimes do it better than we should had we been altogether comfortable and undisturbed during its performance. At the same time, if the distraction becomes powerful enough, we do the thing worse than we should have done, had we been undisturbed. Where are we to draw the line? What is the limit of favorable distraction? There again we are working, and working in good hope of an answer.

I hope now that I have made clear in what sense it is possible to experiment upon mind. Strange as the statement seemed when we first made it, it turns out to be perfectly rational and intelligible. The wonder is, as the wonder always is when a discovery is made, that this discovery of the applicability of the experimental method to the problems of psychology was not made till the middle of the present century. However, the psychologists try to make up for the youth of their science by the enthusiasm with which they pursue their investigations. And that students find the subject interesting is vouched for by the fact that, within the last few years all the universities of note have found it necessary to establish "professorships of experimental psychology" and "psychological laboratories."

MEDICAL TERMINOLOGY—ITS ETYMOLOGY AND ERRORS.[1]

By P. J. McCOURT, M.D.,

NEW YORK.

Mr. President and Fellows of the Academy: Of late, much has been said before this Academy, and much has been written in our journals, advocating the adoption of a common international language for the interchange of professional thought. However desirable such an acquisition may be, the difficulties in the way are so great that we cannot hope for its attainment during the present or even the coming generation. English will be long debarred as a common professional language, by reason of international jealousy. Greek, then, which is the basis of our nomenclature, and also the mother of modern tongues, remains the only valid language for such purpose. But an available knowledge of Greek will demand at least two years' persistent study; and there are many useful men in the profession, as well as many others about to enter it, who could never attain that knowledge. When, however, the effort has been made with apparent success, the student who was taught "Greek" in the universities of English-speaking countries will find, upon visiting Greece, or on coming in contact with scholars from other countries who have learned the language correctly, that he can neither understand nor be understood—that he will not know the pronunciation of one word in twenty. In view of these and other obstacles, it seems a waste of time, for the present at least, to discuss a project so purely Utopian.

It should not be inferred from these premises that a knowledge of such Greek as we can learn in our own country is valueless. On the contrary, it is not only valuable but indispensable. Our terminology is derived primarily from the Greek and secondarily from the Latin. Whatever be the inconvenience of this burden, the rule has been firmly established, and we cannot now alter it. It follows that at least a slight knowledge of these languages is necessary to a comprehension of the words we use. The intelligence and dignity of the profession render this demand imperative. When a new word is required to express a new principle or to modify an old one, we take two or more Greek words from which to construct it. The word thus formed will not give a clear perception of its meaning, save its etymology be figured clearly and picturesquely in the mind of him who employs it. Ruskin long ago entered a sound and eloquent plea for picturesque reading. But many of our terms which have gained a firm hold were formed in this manner by men who were lamentably ignorant of the Greek and Latin languages; and as a consequence the Latinized Greek is often grossly perverted and corrupted. The ancient Greeks, who had not the light of modern anatomy, physiology, and pathology to guide them, gave erroneous names to many parts, functions, and diseases; and these errors have been perpetuated with but slight attempt at correction on the part of the moderns. The same people, especially the Athenians, availed themselves fully of the elastic powers of the beautiful Greek to bestow ludicrous and fanciful names upon persons and things around them; and our language of to-day is affected by the abuse of this privilege. Misnomers must have been coeval with the dawn of our science, if not antecedent to it, since the appellation of "horse-driver" was applied to one of the most gifted of ancient philosophers—a descendant of Æsculapius, the son of Heraclides, the student of Herodicus, and the "Father of Medicine"—Hippocrates, from *hippos*, a horse, and *chrateo*, to govern.

Other difficulties, also, arise in the way of attaining perfection in our terminology. Aside from our yet imperfect knowledge of morbid anatomy, from the difficulty of translating idioms and of finding two or three words in which to describe the characteristic features of a disease, language itself is imperfect and often fails. Even the verb "to be," by which we declare our existence, is an imperfect verb in nearly every language having a grammatical construction. I have compared that verb in twenty-six languages, and in all of these the verb was found to be imperfect.

If, therefore, it be impracticable at this time to adopt a universal medical language, it is both practicable and highly essential to correct and improve that which we now use; and in doing this we must, in order to be understood, follow, to some extent, the erroneous pronunciation taught us. The ignoble defects of our terminology must be manifest to all who have given the subject any consideration whatsoever. Men of no other calling use such irrational and equivocative words when treating of their subjects. It is humiliating to reflect that the cowboys on the plains employ a more intelligent vocabulary for their vocation than we do for ours—one in which men are expected to clothe the highest order of human thought.

The name of a disease must be defective if it does not clearly indicate the pathological change, or the part affected, or both; or, failing these, the characteristic effects of the morbid process—and a vast majority of those in use fail to do any of these. Nor does the evil end here; for a large number of terms delude the student by indicating conditions which do not exist, even in a remote degree. While not a purist in words, or in anything else, I wish to recall to your memory a few among the more conspicuous misnomers in almost

[1] Read before the New York Academy of Medicine, June 6, 1895.

constant use, and to show, by analysis of these, the urgent necessity of reconstructing our terminology.

Acetabulum, Latin *acetum*, vinegar, the vinegar-cup of the ancients, is a silly misnomer for the cotyloid cavity, from *kotyle*,[1] a small cup, and *eidos*, a form or resemblance.

Ague may be from the French, meaning sharp, but far more likely arises from the Gothic root *agis*, to tremble.

Allopathy, allopathist, from *allos*, other, and *pathos*, affection or disease, are terms attached, in derision, to the rational practice and practitioners of the regular profession, to signify that we cannot cure a disease without establishing another disease in its place—which we all know to be an untruth. We should never hear the terms applied without at least correction.

Alopecia, from *alopex*, a fox, instead of calvities, Latin *calvus*, bald.

Anasarca, from *ana*, through, and *sarx*, the flesh; ascites, *askites*, from *askos*, a leather sack; œdema, from *oidema*, a swelling, are all equally childish.

Angina, cynanche, from *kyon*, a dog, and *ancho*, to strangle, is shown by Pliny ("Nat. Historia," viii., 51) to have been applied to sore throat in both dogs and swine. Galen applied the term to laryngitis, while Euripides and Heraclides (Meineke's "Com. Fragmanta") before him had described the disease as *tod anchones pelas*: "'tis nigh as bad as hanging." These generic terms are now happily being superseded by others of more definite meaning.

Aphtha, from *apto*, to kindle, to set on fire—not to inflame, as rendered by Dunglison in his Medical Dictionary.

Apoplexy, *apoplesso*, from *apo*, away, from, or by means of, and *plesso*, to strike, does not tell of hemorrhage on the brain or elsewhere.

Artery, from *aer*, air or spirit, and *tereo*, to preserve or keep, defines a vessel in which air is the last thing contained.

Asphyxia, from *a*, privative or negative, and *sphyxis*, the pulse, describes syncope, but not strangulation, suffocation, or suspended respiration, the proper term for which is apnœa, from *a*, privative, and *pneo*, to breathe.

Atheroma, from *athera*, groats or meal, also gruel, and

Atresia, from *a*, privative—and *treo*, to bore, unbored—both give false ideas of the pathological conditions they are meant to define.

Autopsy, from *auto*, one's self, and *opsis*, the act of seeing, does not necessarily imply, as many suppose it does, self-dissection. Autopsy may, without much strain, signify "seeing or examining for one's self;" but examination of the cadaver is properly expressed by the term necropsy, from *nekros*, a corpse, and *opsis*, from the future, *opsomai*, of the verb *orao*, to behold—not from *optomai*, as given in all our medical dictionaries.

The caprice of naming a disease after the author who has first or early described it is either egotistical or idiotic—egotistical when applied or sanctioned by the author, and idiotic when adopted by others. Such names give no hint of the lesion implied, and can serve only to confuse our students. As results of this folly we have Addison's disease, Bright's disease, Graves's disease, Hodgkin's disease, Ménière's disease, Scrivener's palsy, etc.

Beriberi has been deemed a term of obscure etymology, and is usually rendered from the Singhalese, to imply weakness, intensified by repetition. The verb *beri* (Aryan root *ber*) is pure Hindustani, the Braj Bhasha dialect of the Hindi, which in turn is one of the seven branches of the Aryan tongue still spoken in India. *Beri* means, in both the ancient and modern language of the Hindus, to be fettered or shackled.

Bougie, French, is no longer a "wax candle."

Bronchocele, from *bronchos*, the windpipe, and *kele*, a protrusion or tumor. Goitre, possibly from the Swiss *gutter*, probably from the Latin *guttur*, both meaning throat and equally incorrect.

Bubo comes from *bubon*, the groin, and yet is applied to certain swellings in the axillary and parotid regions.

Cachexia, from *kakos*, bad or evil, and *hexis*, a habit; diathesis, from *diatithemi*, to arrange or dispose; dyscrasia, from *dys*, bad, and *krasis*, a tempering, or temperament: are not all these misleading, incorrect, and vague?

"Cæsarean section" has served to perpetuate an historic fable, since Julius Cæsar was not cut out through the abdominal parietes. The myth had its origin in mistaken etymology: to infants thus born Pliny and others before him applied the term *cæsones*, Latin, from *cæsum*, to cut.

Catalepsy, from *kata*, intensive, and *lambano*, to seize, or to pounce upon, gives not the slightest clew to this condition.

Cataract, from *kataraktes*, to rush down (like a waterfall), might oftener be applied to fluxes than to an abnormal lens condition.

Chemists, it has been complained, are constantly changing their language; but that language is now more accurate than that of any other branch of medicine. It still retains a number of absurdities, however, which ought to be eliminated. Alcohol, Arabic, from *al*, definite article the, and *kahal*, a fine, subtle powder. Alkali, Arabic, from *al*, the, and *kali*, ash (of plants rich in soda); but kali is applied to potassium. From this source we also derive the Arabic-Greek hybrid, alkaloid: literally, "like an alkali," which the alkaloids are not. Cobalt, German, *kobold*, a gnome or demon. Carbolic acid would be better described as an alcohol. Oxygen is not the "acid-generator" which its name implies; many acids contain no oxygen, while all contain hydrogen. Ozone, from *ozo*, a stench. Sulphuric ether—properly ethylic ether, $C_4H_{10}O$—contains no sulphur, etc.

Chlorosis, from *chloros* (the Greek name of the element chlorine), green, is no less senseless than anæmia, from *a*, privative, and *haima*, blood, bloodless.

Cirrhosis, from *kirrhos*, reddish-yellow.

Consumption, marasmus, phthisis, and tabes each mean to waste away, or to consume.

Dengue, Spanish, a short veil.

Diabetes, from *dia*, through, and *baino*, to go.

Diphtheria, from *diphthera*, skin, leather, or membrane: at best, a "disease of the membranes" (formed like the term pneumonia).

Dysentery, from *dys*, difficulty, and *enteron*, a bowel, instead of colitis, from *kolon*, the colon, and suffix *itis*, denoting inflammation of the part designated by the primative.

Embolism, from *em*, in, and *ballo*, to throw: something or anything thrown in.

Epilepsy, from *epilambano*, to seize upon, is quite as silly as *petit mal* and *grand mal* of the French.

Epistaxis, from *epistazo*, to distil up.

Erysipelas, from *erythros*, red, and *pela*, skin. This important term is not derived in part from *eruses*, as Dunglison renders it, since there is no such word in the Greek language, ancient or modern.

In that class of diseases which we may, with some freedom, term eruptive, there is among their names scarce one that has reason in its etymology or suggestiveness in its root. Acne may be a corruption of *akmai*, pimples on the face at puberty; or, better, menstrual dermatosis of the face; but Dunglison follows Cassius in ascribing it to *akme*, vigor—a very unfortunate condition, it must be inferred. Cancer, Latin *cancer*, a crab. Carcinoma, *karkinos*, a crab. Scirrhus, *skirrhos*, hard. Ecthyma, *ekthyo*, to break out. Ec-

[1] Following the course adopted when touching upon this subject in 1880, I have placed the Greek words, like those of other languages quoted, in italics. The terminal *o* in the Greek words given is usually long (*ômega*).

zema, *ekzeo*, to boil out. Exanthema, *exantheo*, to blossom out. Herpes, *herpo*, to creep. Impetigo, Latin *impeto*, to invade or attack. Lepra, *lepros*, a scaly skin. Lichen, *leichen*, moss. Psoriasis, *psora*, the itch, but applied to scaly tetter—in Europe, to the lepra of the Greeks. Rupia, *rhypos*, dirt, filth. Scabies, Latin, *scabo*, to scratch. Sycosis, *sykoomai*, to become like figs. Variola, Latin *varius*, spotted, etc. What are all these to a careful reader but misleading hints to the diseases they are meant to depict?

Gangrene, from *graino*, to gnaw. Necrosis, from *nekroo*, to deaden, to kill, is fairly accurate; and there is nothing in the latter term to restrict its application to bone tissue.

Gonorrhœa, from *gone*, semen, and *rheo*, to flow, is one of the most palpable misnomers we still tolerate. A better term would be blennorrhagia, from *blenna*, mucus or slime, and *rhegnumi*, to burst forth; or, more strictly accurate, blennorrhœa, from *blenna* and *rheo*. Baptorrhœa, from *baptos*, infected, and *rheo*, would be also admissible.

Gout, Latin, from *gutta*, a drop: podagra, from *podos*, a foot, and *agra*, a seizure, are terms whose derivations are laughable, quaint, and wrong.

Gynecology, from *gyne*, *gynaikos*, a woman, and *logos*, the doctrine of. You will remember that in the Greek and Latin languages *o* is masculine and *a* is feminine. Here we have a term purely masculine to designate a condition purely feminine. The correct term should be gynecalogy. Much akin to this paradox, but still more egregious, is the term "Mariolatry," coined by a bigot of divinity to imply worship of the Virgin—which no church teaches.

Hernia, from *ernos*, *hernos*, a branch or offshoot, is certainly misleading.

Hydrophobia, from *hydor*, water, and *phobos*, dread or fear, so named from one of its occasional symptoms, instead of the condition, which is that of rabies, Latin *rabio*, to be mad or to rage. But the correct term is lyssa, from *lyssa*, rage, madness; also the worm under the tongue of dogs, believed to produce madness (Pliny, xxix, 32).

Hypnotism, from *hypnos*, sleep.

Hypochondriasis, from *hypo*, under, and *chondros*, a cartilage, gives, vaguely, a locality where is an organ which may be, at times, the cause of the condition announced in the misnomer.

Hysteria, from *hystera*, the womb, should have immediately been discarded for a more rational term when well-marked cases were first observed in the male. Yet, in view of this familiar fact, Dr. Barnes has proposed a name nearly as vague as the old one—"oöphoria," from *oon*, ovum, and *phero*, to bear—based upon the hypothesis that the ovaries and not the uterus are the seat of this neurosis.

Hybrid terms, each formed from two languages, were justly denounced by the ancient Greeks as *hybris*, lawless, violence, wantonness. This mode of word-building, at once constructive and destructive, is a vice which even ignorance cannot excuse. As examples of these hybrid terms we have albuminuria, from Latin *albus*, white, and Greek *ouron*, urine. Fibroid, from Latin *fibra*, fibre, and Greek *eidos*, appearance or resemblance. Terminology, from Latin *terminus*, a term, and Greek, *logos*, a discourse or treatise. Tuberculosis, from Latin *tuberculum*, tubercle, and Greek *osis*, denoting formative process, etc. We might with as equal propriety say throatitis as vaginitis.

Idiocy, from *idiotai*, private citizens, not office-holders.

Influenza, Italian, influence (of the stars).

Laparotomy, from *lapara*, the loins, and *tome*, a cutting or incision; properly, incision for nephrectomy, and not abdominal section, the correct term for which is cœliotomy, from *koilia*, the abdomen, and *tome*.

Laryngismus, from *laryngizo*, to shout loud or often. The secondary meaning of spasm sometimes attached to this suffix cannot redeem the error.

Lithotomy, from *lithos*, a stone, and *temno*, to cut. As Campbell naïvely points out, it is the bladder, not the stone, that is cut; and he suggests the correct term, litho-cystotomy.

Lymph, Latin *lympha* (from Greek *lymphe*), clear water.

Malaria, Italian, from *mala*, bad, and *aria*, air, illustrates how a number of diseases have been named from their causes instead of their effects.

Malignant, Latin *malus*, bad or evil, is but little worse than its equivalent, virulent, Latin *virus*, a poison, which, in turn, is derived from Sanskrit *veshas*, a filthy poison.

Mania, from *mainomai*, to rage—akin to *men*, the moon, and equivalent to the Latin *lunaticus*, from *luna*, the moon—are examples of ancient superstitions to which we still cling.

Melancholia, from *melas*, *melanos*, black, and *chole*, bile, is not remarkable for lucidity.

Myopia, from *myo*, to shut, and *ops*, the eye.

Neurasthenia, from *neuron*, a nerve, and *asthenia*, absence of strength—although the nerves would seem to have acquired, or at least transmitted, all the strength and activity of the body.

Nymphomania (see gynecology), from *nymphe*, a maiden, and *mania*, should give place to andromania, from *aner*, a man, and *mania*. *Nymphe* cannot be translated by the word clitoris, as Dunglison has done, and nowhere in history has the noun been so used.

Pancreas, from *pan*, all, and *kreas*, flesh, might have been applied with some excuse to the misnamed prostate (from *pro*, before, and *istemi*, to stand), which contains but little if any adenoid tissue.

Paralysis, from *para*, beside, and *lysis*, from *lyo*, to loosen.

Paresis, from *pariemi*, to relax, or to misdirect.

Phlegmasia dolens, from *phlego*, to burn, or *phlegmazo*, to inflame, and Latin *doleo*, to be in pain; either but poorly describes what ought to be called obstructive phlebitis.

Phrenitis, from *phren*, the mind (properly, the midriff or diaphragm, also the heart, but never denotes the brain), and *itis*. Encephalitis, from *en*, in, *kephale*, the head, and *itis*, has been more generally sanctioned; but meningo-cerebritis is less faulty than either.

To treat of the "physiological" action of drugs upon the body, instead of their pathological, pathogenetic, or toxicological action, is an abuse of language.

Pneumonia, from *pneumon*, the lungs, and terminal *ia*, denoting a morbid condition of the organ named: a "disease of the lungs," should be replaced by pneumonitis, or even pulmonitis.

Polypus, from *polys*, many and *pous*, foot.

Quarantine, Italian, from *quaranta*, forty (days of exclusion).

Ranula, Latin dim. of *rana*, a frog.

Rheumatism, from *rheuma*, a flux, catarrh, or diarrhœa, merely implies an indefinite morbid humor in the body, but gives no intimation of change in muscular, articular, or synovial tissues.

Scorbutus, Teutonic, from *schaar*, torn, and *buuk*, the abdomen.

Scrofula, Latin *scrofa*, a sow with many young; correct only by inference that the disease is common to swine and to those who eat of their flesh.

Surgeon, surgery, from *cheir*, the hand, and *ergon*, work or exploit—although the essence of the "exploit" is brain-work.

Syncope, from *syn*, intensive, and *kopto*, to cut, to cut short.

Syphilis; "etymology unknown" or "uncertain" is the comment of most lexicographers. That given by Blancardus—*syn*, together, and *philco*, to love—was

for some time accepted by many. But there is little room to doubt that its true derivation is from *sys*, a swine, and *phileo*, as given by the poet-doctor Francastoro in his medical poem, "Syphilidis sive Morbi Gallici," libri tres, Verona, 1530, one of whose characters, a swineherd, contracted the disease. But neither term describes the lesion.

Tetanus, from *teino*, to stretch; so named, doubtless, because the condition is just the opposite, that of muscular contraction. Trismus, from *trizo*, to grate or gnash the teeth, is equally faulty.

Tic douloureux, French, painful twitching.

Nowhere does greater chaos reign than among the names of fevers; but we shall only consider that of typhoid, from *typhos*, stupor, and *eidos*, a form or resemblance; literally, "like typhus," which it is not. Enteric fever, from *enteron*, an intestine, is equally inappropriate. The term suggested by Murchison, pythogenic fever—*pythogens*, from *pytho*, putrid, and *gennao*, to generate, "born of putridity"—while not correct, is the best yet offered.

Zymotic, from *zyme*, leaven, or from *zymosis*, a ferment. Both forms are, like many of the others given, so ambiguous as to call for no criticism.

Let us now compare the foregoing jargon with terms which are technically correct, which clearly describe the lesion implied, and the contrast will be worthy of note.

Endocarditis, from *endon*, within, *kardia*, the heart, and *itis*, denoting inflammation.

Hæmatemesis, from *haima*, blood, and *emeo*, to vomit.

Hydropneumothorax, from *hydor*, water, *pneuma*, air, and *thorax*, the chest.

Retroflexion, Latin, from *retro*, backward, and *flecto*, to bend.

Is it not possible to render the whole, or nearly the whole of our terminology as accurate, beautiful, and explicit as this? It would seem that the time has arrived when such advance can be made, and that the profession is ready to accept it. Scholars and men of science should no longer be forced by ancient rule or modern error to speak in childish prattle, nor to perplex themselves and those who are to follow them by the use of terms which falsify their meaning. The reconstructive process, however, cannot be intrusted to the compilers of medical dictionaries. It is not the lexicographer who makes a language, but the scholars who speak and write it. Hence the reformative effort, to achieve success, must be collective and made in unison, and not merely individual. If this Academy, as the leader of professional thought on this continent, will take the initiative, its action will be readily seconded by medical journals and college professors; and soon our terms will be made to reveal ideas which they now conceal, pervert, or obscure.

From this mongrel tree of philological blunders I have plucked but a few of the withered leaves. I could wish that the office had found one who was also competent to do the pruning. That portion of the work will need for its execution the united efforts of expert pathologists and Greek scholars—and I claim no place among either.

233 West Twenty-third Street.

Russian University Students.—Russia has only 14,619 university students, with a population of 130,000,000, according to the *Russkaya Schkola*, or 120 to a million, while Germany, with 50,000,000 inhabitants, has 25,000 students. Moscow is the largest university, with 3,967 students; St. Petersburg comes next with 2,675. The 1,176 at Warsaw are almost exclusively Poles, and the 1,555 at Dorpat, Germans.

Chloroform vs. Ether.—Professor Gurlt, of Berlin, has found that in 31,803 cases of chloroform narcosis, 23 deaths occurred, and in 15,712 cases of ether narcosis, 5 deaths.

THERAPEUTIC PROGRESS—A SLOWER PACE NECESSARY.

By R. ELLIS, M.D.,

DANBURY, CONN.

It is necessary for the medical profession to observe how much medical "hash"—of a poor quality, too—is continually being served to the medical public; hash of so conglomerate and miserable a mixture as to sicken any normal digestive process. The journals in which the hash is served are the best published, edited by the best, and read by the most; yet the pages are full of medical food of so poor a quality as to absolutely prevent any medical growth.

One contributor writes, "Away with ergot," and sums up his conception of its therapeusis by stating it should never be used. Can it be possible, after so many years of ergot use, that we do not all agree as to its therapeutical applications?

Another writer discusses the "eliminative treatment of typhoid fever," while another, after so many have buried and forgotten the "cabinet," writes favorably on "the cabinet treatment after six years of experience."

Why, in the name of Æsculapius, can we not agree as to the therapeutical indications for the cabinet? Why will ninety-nine sell their cabinets for a song, believing them to be of no value, whereas the hundredth, after "six years of experience," speaks highly of it? Can we not advance in a better and more scientific way than this? Can we not agree, all of us, once and forever, as to the therapeutical value of this cabinet, and then go on to another subject, rather than be forced every few years to return to an incompletely explored field abandoned for a new fad? Did the ninety-nine fail to secure benefit through faulty technique? Then let the hundredth man explain his technique to the others until we all agree that in such and such cases such results follow from cabinet treatment—then we are ready for the next step forward.

Another writes of prescribing large quantities of water in typhoid fever, even to six quarts a day. Well, that's an idea! You say you have tried it. On how many cases? If on a goodly number, so that you have the right to take up our time (which you do by presenting the subject to us in the magazine we read), let us take this subject and stick to it until we settle the point, and then let no one ten years from now startle the profession by writing a new article on "Treatment of Typhoid by Giving Six Quarts of Water Daily." Let him begin his investigations from the point where we ended, not take up our time by carrying us over an old abandoned road.

Of recent writers in reference to the treatment of peritonitis, some favor salines, others the Clark method, while still others say "first salines, then opium." Well, now that this important question is open for discussion, let us keep it open until we are ready to shut it, and then let us keep it shut. Can we not do this in ten years, or twenty, or even a hundred years, after observing and recording thousands of cases? Can we not then, after so much study and observation, summarize the treatment so scientifically as to prevent anyone from going back again to the very beginning?

We have used ergot for hundreds of years, and we have been led to believe that we knew how and when to use it; but now we are going back again, and soon many will proudly say, "I never give ergot," then new discussions will arise, and twenty years from now we shall have an ergot era. Can we not once and for all give the therapeutical indications for ergot and then stick to them? If not, then let us agree to this statement, "At present the profession has not yet definitely established the therapeutical indications for ergot," and let the question remain open until we can and do agree.

I notice another writer advises against vaginal examinations in labor, and that several have followed in

his footsteps. Well, that is strange, indeed! Can we not all agree that a vaginal examination *is* necessary, and that palpation is *not* all that is necessary? It would seem so, but here and there one catches the disease and the result is a series of articles against any vaginal examination. If these writers really mean what they say, then let us throw open the question until we can agree, and then let the question remain closed unless someone has something of value to offer—some suggestion proved and of real value.

Again, another writes on determining the sex of a child before birth, and soon a volume is produced explaining how parents may show nature how to produce a male or female child at the pleasure of the parents.

Stuff and nonsense! Have we not lived long enough and developed the science of medicine far enough to know that no one can decide or make sex? Yet how many articles have been written on this subject, everyone of them carrying us back again over the ground thoroughly travelled. What sane man can but believe that the ovaries contain male and female ova, and that no foolish action like a sitz-bath or an excess of maternal passion, etc., can possibly exert any influence on sex? Can we not agree on this question? Well, then let us look into it and settle it once and forever, and then let us not open the subject again because Dr. Curious knows of a case where a woman stood on her head before intercourse, and as a direct result of this all of her thirteen children are boys. Open the question to such an observer, and as sure as fate all over the medical field others will relate their experience, and soon a book will appear—probably a "tome" entitled "The Maternal and Paternal Conduct before a Male or Female Conception." Now a writer, pleased with hypodermatic medication, states candidly: "The time is at hand when direct circulatory therapeutics—the transfusion or injection of accurately dosed assimilable or aseptic remedies—will be deemed alone worthy of the attention of practical physicians, whose aim is to prevent and cure disease without doing injury." Is the time at hand? All but the writer agree it is not; then why did the writer say it was when he himself knew it was not? What right has he to waste our time by presenting to us any such nonsense? Why did the editor of this publication accept any such article when he knew it simply filled space? Better leave blank pages than fill them with medical nonsense.

In the treatment of typhoid fever various writers have recently favored large quantities of water, the dieting plan, the expectant plan, the starvation plan, the bathing plan, etc. Can we not some time, some way, reach definite conclusions in reference to the treatment of typhoid fever, and then stick to them? Why should writers present methods of treatment tried in a few cases, when we all know there are a million things that may be tried? We do not care to read what has been tried in a few cases so much as to read about some one sensible plan tried in many cases.

If the Brand bath treatment shows a mortality of ten per cent. out of 19,000 cases, is that not enough? Does this large number not furnish sufficient proof to make us all agree to this method. If not, let us keep this question until we do agree—let us not drop the subject for a few years and then review the whole matter again from the very beginning with fresh details, only to drop it for a new fad and then take it up again.

Can we not agree that starvation treatment in typhoid fever, is very highly injurious and fatal? Now! Then let the writer of this article and others who believe in his stock starve their patients until we can agree, and then let us agree all the time. At present we all agree that no medicine cures typhoid fever, and that therefore we are limited to expectant therapeutics: from this stand-point if we launch out at all, let us follow one path to the end; if 19,000 cases under the Brand bath treatment prove nothing, let us keep on the journey till we have, if necessary, nineteen million cases to prove the value of this treatment. From this vantage-point, if anything new develop, let us follow it out until we reach the end, but pray let us begin with the nineteen million cases and not from the beginning again. Sad it is to see us drift out a few feet on the starvation journey and then return; drift out on the specific treatment by calomel, carbolic acid, and iodine, and then return; drift out at the summons of anyone and again return. Pray let us follow *each path* until we reach the end or are forced to return in confusion: and then let us, as a profession, remember the long journey and profit by our experience. If anyone has an "idea" let it start from the end of a previous journey (if there was one) and not, we pray you again, from the very beginning.

Another writer says in a recent journal: "I can say that a careful trial of forced feeding in certain cases of scarlet fever, diphtheria, typhoid fever, etc., will convince anyone of its very great value." Here is another "idea:" we believe in a simple nourishing diet in all acute diseases, but now we have something new. On what grounds does this writer favor forced feeding? Has he reasonable ground for taking our time as he presents to us his new idea—yes? Then let us stick to this suggestion until we have pressed out all the meat, and then let us keep it fresh before us. We hope the writer will not retrace his steps and then "spring it on us again," but that he will now tell us just what "certain cases" are greatly benefited by forced feeding. Again, in the same journal a writer states that "mycodermic medication by means of hypodermic injections of yeast fungus which continues to live in the tissues and destroys pathogenic bacteria by phagocytosis, are of very great value. Among a large number of tubercular patients ninety per cent. were cured in the earlier stages; sixty-five per cent. of phthisis in the second degree. This result was reached in five thousand cases." Is this statement true? then we who believe there is no specific for phthisis and follow our belief by prescribing only fresh air and good food, are criminally negligent in not using the yeast fungus which cures from ninety to sixty-five per cent. But again I say, is this statement true? We all believe it is terribly false, but we don't know it to be so. If it has been tried in over five thousand cases with such flattering success, I am sure it is our duty to immediately take up this new treatment and stick to it until we know "where we are at."

We must acknowledge that each writer loads his gun with a new idea, hurriedly fires it, and then, without stopping to examine the effects of his first random shot, hastily loads and fires again some new idea. Can we not boast of better soldiers than these—after a medical warfare for centuries? can we not show better marksmen? must we always fire at random and keep on firing without any plan or result?

In the next journal I read that "immunized serum has a true vaccinal action in tuberculosis—in three hundred cases at least a temporary cure was secured." This is the second random shot following the yeast fungus shots. Pray shall we not, after such an effort, give the command "cease firing," and begin to study the effect of these shots, firmly ordering that whoever fires another one shall himself be actually shot?

Another journal advertises "animal extracts" from "cerebrine" to "ovarine"—everywhere these snap shots are being tried, and successfully so, judging by the statements of some writers. One writes that he gave a highly intelligent sterile lady five minims daily of ovarine, and that the menses were "established" in three weeks. He also cheerfully states he will continue the ovarine until the lady is pregnant, making me think of the young son of a friend who, receiving the promise of a watch, replied by letter that he was "extremely delighted with the watch which was to be given to him." Kindly allow me here to fire a shot: I hereby bring to the notice of the profession the following animal extracts—mucine, gelatine, chondrine, elastine, and

keratine. We all know what they can be used for—mucine, for the catarrhal diathesis; gelatine, for bone weakness; chondrine, for cartilaginous irritations; elastine, for that "tired feeling;" and keratine, for loss of hair, thin splitting nails, etc.

Stuff and nonsense! Let us acknowledge that in charging the enemy with animal extracts we have made an over-zealous charge and fired too many random shots. Let us go back again, load up fresh, all of us, with, say, thyroid extract or *some* extract, and then let us keep firing the same gun and the same ammunition until we know again "where we are at."

At the last medical congress in Vienna six methods for treating pyothorax were presented, namely, expectant, aspiration, aspiration and injection, permanent aspiration, simple incision, and resection of one or more ribs; opinions were divided as to the best treatment in the majority of cases—that is what we wish—the question remains open. Many favor free incision, more favor resection—possibly in years to come we may agree, but we are meanwhile studying and heaping up evidence and still clinging to these same forms of treatment, because they are mechanical and "there is nowhere else to go."

In therapeuses it would be well if we were thus mechanically forced to limit ourselves to few measures well tried before taking up new fads; humanity would not suffer if we should do so—it would gain.

Still another writes "that a hypodermic injection of morphia one-fourth grain, one-half hour before giving chloroform, always maintains the heart and respiration." Always? My last journal gives a case of a death under just this condition; therefore the writer will kindly remember one exception to his "always."

In the treatment of gonorrhœa I read of one who recommends nitrate of silver, gr. ij. to gr. lx. to the ounce, applied carefully, care being taken that the bladder is full of urine; another in the next issue of the journal advises injections of from one grain to one-eighth per ounce, and says even very weak solutions are liable to be followed by a violent reaction. This is interesting; the discussion is an open one—let it be so until we can agree.

In diphtheria, we have a new fad—"antitoxin"—let us all notice carefully just how much time and study we are to give this new treatment. We may have a remedy of great value—we hope we have—but let us cling to the new fad until we have squeezed it dry, if there is juice in it. I myself believe we shall be eagerly following a new "idea" in a very few months, possibly weeks.

Recently a monograph, "new and important," in reference to the bacteria of peritonitis, has been published. After a long statement of the different bacteria, the pamphlet sums up by saying: "The number of bacteria found in a single case varied from one to nine: a feature of special interest is the study of thirty representations of the bacillus coli communis with reference to their various cultural peculiarities, number of locomotor organs, and other characteristics; the result shows scarcely any two of them are alike, and we find these thirty representations divided into twenty varieties. Other important and non-pathogenic bacilli were discovered resembling the Klebs-Loeffler bacilli, but another observer states he believes there are as many pseudo-diphtheria bacilli as there are observers."

"No conclusion as to prognosis can be drawn from a bacteriological examination, yet where no bacteria can be demonstrated it would seem that the result is in general more favorable than in those where bacteria are present." In other words, summing up this "new and important" pamphlet from a bacteriological standpoint, in peritonitis we may find bacilli and then again we may not. Such pamphlets should not be published; they accomplish nothing but to weary and disgust their readers; just as if Mr. Stanley in his last book should force us to read a long-drawn-out account of the weight of each stone he passed, the height of every tree, the number of branches to every tree, the exact number of mosquitoes seen, etc. We do not care about such trifling details, we are hungry for facts, and Mr. Stanley gives us facts and leaves out foolish and useless details. Again, in the same journal I read of a report of two cases where, after sodium, calomel, and quinine failed in a treatment of five days, antikamnia and salol were tried, resulting in convalescence in twelve days. From these two cases the author reaches the astonishing conclusion that "salol, as an internal antiseptic, combined with the antipyretic qualities of antikamnia, promise all that can be desired in the treatment of low and continued fevers with bowel complications." All that can be desired! What a statement after an experience with two cases! Just how much does such a statement weigh, and how much does it influence a careful reader? May I not state truthfully that such statements insult careful readers who deny themselves pleasure to gain time to extract meat out of medical journals.

Hello! here's a new treatment for pneumonia! The intra-cellular injection of serum taken from a convalescing pneumonic case. Serum? All right, but let it be serum, until we know "where we are at" with serum. Some praise its use, others assert its influence is absolutely *nil*, among these being a hospital physician, who says, "In the few cases I have seen treated the results were *nil* under serum treatment;" wisely, then, does he advocate "quinine and antikamnia," and criticise the use of large doses of digitalis. These statements of this young interne weigh nothing and accomplish nothing, save to provoke us for the time lost in wading through such useless stuff.

Is it possible that, after years devoted to the study of pneumonia, the profession runs away to the new suggestion "serum"? What right did the serum advocate have to present his newly-born babe to us before it had its clothes on? Why must we be bored and tortured by so many "schemes" and "ideas," when we all know absolutely that we cannot carefully study so many at one time? Why not stick to the old way until someone proves conclusively that he has a new and tested therapeutical measure? While writing these very words, a leading journal which the mail has just brought me introduces me to another new "idea." A physician noting that earth-worms digest mud believes they must possess the property of dissolving urinary deposits: he therefore (without any personal investigation) advises us to select ten or twelve worms which have digested all the mud they can, boil for one-half hour in one-half a pint of water, and give this soup to the patient in one dose. His closing suggestion is, "If this soup is found to be useful, well-known chemists in Europe and America would prepare an extract," for which he proposes the term "Extractum lumbrici terrestris." Horrible and preposterous nonsense! This is not putting the cart before the horse, but attempting to hitch up when there is neither horse nor cart, yet this writer signs himself unblushingly, L.R.C.P.&S.Edin.

Now kindly allow me to present a brilliant idea. Since tape-worms absorb intestinal secretions which are of value in digestion, I propose for intestinal indigestion "Tape-worm soup." If this is found to be of value I would name the extract "Extractum tæniæ solii" and hereby claim whatever credit may arise from this brilliant discovery.

Pray, can we not work in a more scientific way? Should we not do so? Must we not do so if we expect to make any real advance?

We can prepare medicine from every imaginable thing, from everything *conceivable* outside of the body to everything *conceivable* inside of the body, and apply these innumerable remedies for every conceivable disease. We know this to be true, and therefore we should give little credit to anyone for proposing serum in pneumonia; "liver extract" for the diseases of the

liver; "spleen extract" for the spleen; typhoid serum for typhoid fever, etc., to an infinite variety of suggestions.

Anyone can make suggestions, *millions* of them if desirable; but we don't need "suggestions," we sadly need facts; we are nauseated with many "newly hatched, unfledged ideas;" we are starving for tested and proved therapeutical facts.

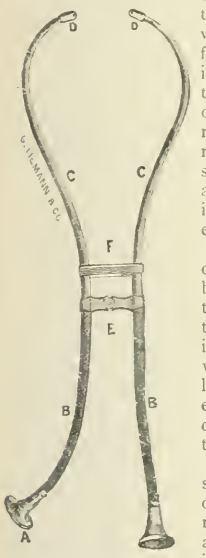
THE USE OF THE DIFFERENTIAL STETHOSCOPE IN THE STUDY OF CARDIAC MURMURS.[1]

By ANDREW H. SMITH, M.D.,

NEW YORK.

ALTHOUGH usually the auditory impressions made upon the two organs of hearing are blended together and are perceived by the sensorium as one, it is possible, by a little training, to acquire the power of separating them, compelling the sensorium, as it were, to take separate cognizance of the perceptions received through one ear, as distinguished from those received through the other.

To do this, however, the sound waves must reach the drum membranes through different and distinct channels. This is effected by the differential stethoscope, which, in its simplest form, differs from the ordinary binaural instrument simply in having two thoracic extremities instead of one, each connected with its respective ear-piece. This arrangement enables us to hear separately two sounds produced at the same time in two localities more or less distant from each other.



An analogous effect is produced when a piece of cardboard is placed edgewise between the eyes. In this case the visual field for near objects is divided, and though the advantage of binocular vision is lost, it is possible with a little effort to take cognizance of two distinct visual impressions at the same time.

The field in which this stethoscope is useful is a restricted one, but within that field it may render essential service. Its aid as a differential instrument is important in determining the time, rather than the quality, of sounds heard in different cardiac localities. We have no practical difficulty in appreciating even a slight dissimilarity in sounds which are separated by short intervals. We can, therefore, with the ordinary stethoscope change the instrument from one part of the cardiac area to another, and compare satisfactorily the quality of the sounds we hear.

Under normal conditions the difference in character between the first and second sounds of the heart is enough in itself to distinguish them from each other, independently of the element of time. But cases occur not infrequently in which neither the character nor the time of the heart-sounds is available for this distinction. In these cases the quality of one or both of the sounds is masked by the presence of a murmur, or so modified by conditions of vascular tension as to be unrecognizable, while at the same time the intervals embraced in the cardiac cycle, instead of being unequal, have the same duration. This latter condition occurs whenever the heart's action is greatly accelerated, as the increase in frequency is chiefly at the expense of the longer interval. At the same time, with such a rapid action, it is impossible to tell which of the alternate sounds corresponds with the apex beat or the carotid pulse.

Under these conditions it is manifest that, if we find a murmur at the apex, and by shifting the stethoscope we find another at the base, we shall be utterly unable to tell whether the two occur simultaneously or successively. And yet the entire question of how the signs shall be interpreted hinges upon this point. Supposing a lesion at each orifice, then if the murmurs are synchronous, one must be direct and the other regurgitant. If, on the other hand, they are alternate, then both must be direct or both regurgitant.

Now, whatever help it would be to us in the solution of the problem to know whether the two murmurs are produced at the same time, or first one and then the other, that amount of help we can get from the differential stethoscope. If we place one extremity over the apex and the other over the aortic area, we shall know at once what is going on in each locality with each period of systole and diastole. If we hear a murmur with each ear at the same time, we shall know that the two murmurs are produced by the same act of the heart. If we hear a murmur alternately with the right and the left ear, we shall know that one occurs with systole and the other with diastole.

I have seen lately two cases of combined mitral insufficiency and aortic stenosis in which the differential stethoscope showed that the murmur at the apex preceded that at the base by a very appreciable interval. The systole, therefore, was well under way before the blood began to flow through the aortic orifice. This is easily understood when we consider that the ventricle must contract sufficiently to occasion a pressure within it in excess of that in the aorta, before the blood will move in the direction of the latter. The leakage through the mitral orifice opposes this result and delays the moment at which the intra-ventricular tension reaches and exceeds the pressure upon the semilunar valves. During this interval of delay we have the murmur of regurgitation, but not the stenotic murmur. As the delay is proportioned to the amount of blood flowing back into the auricle, the interval between the murmurs is an accurate measure of the incompetency of the mitral valve.

Reduplication of one or other of the cardiac sounds is of frequent occurrence, and has been explained in a variety of ways. A favorite theory has been that it was due to a want of synchronism in the action of the ventricles. This point could be determined by simultaneous auscultation of the tricuspid and mitral, or of the pulmonary and aortic areas.

Within the past week I saw a case which the day before had presented well-marked reduplication of the second sound as observed by the physician in charge. This was no longer present, but the differential stethoscope showed a marked lagging in the contraction of the left ventricle as compared with the right. At the same time, the aortic second sound was sensibly later than the pulmonary. An exaggeration of this condition would have constituted reduplication.

The successful use of the differential stethoscope requires a fairly acute and well-trained ear, with no difference in the hearing-power between one ear and the other. Some practice in this special form of auscultation may be necessary to acquire the power of giving separate yet simultaneous attention to the impressions which each ear receives.

Among Educated Germans no less than sixty-seven per cent., so the statistics say, have imperfect or defective eyesight.

Clinical Department.

REPORT OF CASES IN BRAIN SURGERY.[1]

By DOUGLAS C. RAMSEY, M.D.,

MOUNT VERNON, IND.

PRESIDENT INDIANA STATE BOARD OF HEALTH; MEMBER AMERICAN MEDICAL AND PUBLIC HEALTH ASSOCIATIONS, AND MISSISSIPPI VALLEY AND INDIANA STATE MEDICAL SOCIETIES.

Case I.—A. O——, aged twenty-five. Residence, Mount Vernon. April 7, 1891, was grinding a moulder's knife on an emery wheel making over two thousand revolutions per minute, when the wheel burst, striking him in the left frontal region and causing an extensive laceration of the soft parts, a compound comminuted fracture of frontal bone, and tearing away brain tissue the size of my thumb. I was called to see him at once; found him at a planing-mill, where he received the injury. He was propped up in a chair, having recovered consciousness. I placed a clean towel over the wound, ordered him carried to his boarding-house, four squares distant.

Assisted by Dr. J. W. Powell, I then proceeded to treat the injury antiseptically, cleansing the hands and injured parts with a hot bichloride solution, sensibility being sufficiently stunted to dispense with an anæsthetic. I removed detached brain matter the size of my thumb, twenty-five spicula of bone, some driven into the brain over an inch; elevated some depressed bone; removed comminuted portions of supra-orbital arch; one-half of same, an area of about two and one-fourth by one and one-half inch of bone, was removed. The very considerable hemorrhage was controlled by pressure and packing. I then closed the soft parts with catgut, sublimate gauze, and cotton, with sublimate gauze bandage over all, leaving dura open—so much being destroyed it was impossible to close gap in same—and leaving catgut bundle for drainage at lower angle of wound. The brain pulsated at site of wound. Wound healed by first intention. Drains were removed, one at a time, until last were removed on the sixth day, and wound closed complete by tenth day without any rise in temperature. Patient was out on the street thirteenth day. There was loss of sight in eye on side affected. Aside from this a perfect recovery ensued. He is now a carpenter and contractor in active service.

Case II.—R. C——, aged thirty-four. Residence, Mount Vernon. Presented himself, August, 1893, with the following history: Was injured fourteen months previously by being struck on head with a brick, which produced unconsciousness and was followed by epileptic seizures. He was trephined by his attending surgeon, some depressed bone elevated, and a small portion of brick removed, with improvement for two weeks' time. Epileptic convulsions then returned, occurring several times weekly and frequently several times daily. When I saw him he had distinct tremor of left arm.

August, 1893, assisted by Dr. Dixon and others, I trephined (button of bone removed being one-fourth inch thick, probably due to inflammatory changes) on right side of head at site of injury, and with rongeur removed all bone which could not be elevated into proper position, removing bone to extent of about two by one and one-half inches. Wound united in five days without suppuration or any rise in temperature. Dressing used: Catgut sutures in scalp, dusted line of sutures with iodoform and bichloride gauze, and sublimate cotton with sublimate gauze bandage over all. No drainage. Has never had any return of epileptic seizures, and is in robust health.

Case III.—H. F——, aged nineteen. Residence, Poor Infirmary. When seen presented the following history: Four years before was injured in head by a falling tree. One year after that was re-injured by being hit on head with a club. Had epileptic seizures from time of first injury, several a week, and sometimes two or three daily. Was trephined by a surgeon in Missouri shortly after last injury was received, without benefit. Site of this operation, left side of the head. Had distinct tremors of left arm.

September, 1894.—Assisted by Dr. S. H. Pearse, I made a crescent-shaped incision on right side of head and trephined near site of injury. Found a very large area of depressed bone, which was with difficulty elevated into position. Then removed some depressed spicula with forceps. Operation was done antiseptically, all oozing checked by pressure and flaps stitched with catgut. Dusted line of sutures with iodoform and bichloride gauze, dressing with sublimate cotton and sublimate gauze bandage over all. No drainage. Thirty hours after temperature rose to 103½° F., with intense headache. Gave 5 grains antikamnia and ¼ grain morphine. Temperature fell to normal within two hours and never rose above same again. Wound healing by first intention in five days. No return of convulsions for three weeks, at and since which time he has had from time to time hard epileptic seizures. I do not believe this patient has been benefited by the operation, for the reason, perhaps, that there was at time of receipt of wound irremediable injury to the brain substance.

Deductions.—Case I. is illustrative of how little permanent disability for performance of manual labor may result after serious injury and considerable loss of brain matter.

Case II. shows the good results that trephining will sometimes accomplish when performed for traumatic epilepsy.

Case III. indicates how little relief is sometimes obtained in trephining for traumatic epilepsy.

IRRIGATIONS IN ACUTE GONORRHŒA.

By W. A. DAVISON, M.D.,

FORT BENTON, MONT.

In an extract from a lecture in the Medical Record of June 1, 1895, Dr. Rantier says: "When the gonorrhœa is in the acute stage I would advise not to interfere. Tell the patient to wear a suspensory bandage, to take an alkaline bath every three days, and in about ten days afterward to come back, and then you will cure him." This might do in great medical centres in France, and possibly even in the medical metropolis of the United States, but the medical man in this section who prescribed such a course in the treatment of his cases of acute gonorrhœa would most assuredly treat very few cases of this disease. My plan is to treat gonorrhœa at any stage. Why not? If we will adapt our remedies to the stage, physical condition, and individual peculiarity of patient, I fail to see why we should leave nature to struggle single-handed with her adversary until she had well-nigh conquered. We do not hold our hands in the acute stage of inflammatory affections of other organs, and why this? I think the hot-water irrigations equally adapted to the acute stage. I begin them the very first day the case presents itself, and know of no treatment better than the action of hot water. I use a good-sized fountain syringe well filled with hot borated water—well filled, for thus the heat is retained during the entire time necessary to make a proper application. To the pipe attach a glass tube, and over the end of this for two inches draw a soft rubber catheter; anoint well with carbolized vaseline or oleate of cocaine, if the parts are very much irritated, or better only sensitive; and here one may easily overestimate the amount of hyperæsthesia, for one may often pass this catheter, causing very little pain. Introduce

the catheter carefully one inch, turn on the hot borated solution, and after you are satisfied all is clean as far as you have gone, very gently and gradually push your catheter into the deeper urethra, and even into the bladder, if one's judgment deems it advisable, allowing, all this time, the water to flow out all around your catheter. The object is to thoroughly cleanse the urethra as you enter. Your fountain should not be elevated more than two feet above the patient. These irrigations should be repeated at least daily, and at least a quart of the hot solution consumed; often two quarts is better. Follow these irrigations after two hours' time with some soothing mucilaginous sedative injection of not more than half a drachm thrown gently in, and repeat each six hours in the acute stage; but in the subacute or chronic I like the morphia and zinc better than anything I have yet tried.

℞. Morphia sulph..... ℈ iv.
Zinc acetate..... gr. j.
Aqua..... ʒ iv. ad vj.

I have pursued this plan of treatment for several years, and with commendable success. The patient will pass out of his physician's hands with a grateful heart and free from stricture.

A CASE OF ACUTE LARYNGITIS.

By M. E. HUGHES, M.D.,

ADAMS, MASS.

It was only on noticing an account of Dr. Charles S. Dickinson's case of the above complaint, as related in the Record of June 1st, that I decided on narrating the experience I was then having with a similar case.

June 3d, I met, socially, Mrs. R. B——, aged twenty-nine years. She complained of a cold contracted two days before. The symptoms at that time were a dry cough and some hoarseness of the voice, which latter, she stated, had been first noticed that morning on arising. She also stated that, from her knowledge of the course of previous attacks, she believed the hoarseness would become more and more pronounced quite rapidly. Generally, she felt about as usual.

About two hours later, on taking my leave, she said that she experienced some difficulty in breathing, and that she believed that this too would increase rapidly in severity. It was now evident that her prediction regarding the hoarseness was quite true. This was about five o'clock in the afternoon (5 P.M.) I left her, saying that I would return later and endeavor to relieve her.

At 9.30 P.M., on my return, I found her sitting on the edge of a couch, her hands down by her sides and pressing firmly against the couch, body bent slightly forward, eyes bulging, face wearing a pinched, anxious expression as if in fear of some great danger against which she was utterly powerless, and suffering from great dyspnœa. There was no cyanosis.

I was told that at times, since I had left her in the afternoon, she had suffered from exacerbations of this dyspnœa which an attack of coughing would relieve somewhat, but not so decidedly as when the coughing was followed by the expectoration of a thick, mucous-like substance. Pulse very rapid. Temperature in axilla 100° F.

I at once sprayed the throat well with a four per cent. solution of cocaine, cautioning her against swallowing the least particle, if possible. In spraying I endeavored to force as much as possible into the larynx. In ten minutes there was a very noticeable relief from the dyspnœa, in thirty minutes the breathing was perfectly normal, not the slightest evidence of distress, and the face had assumed its wonted expression.

I then ordered ♏j. of the tinctura aconiti radicis every hour.

She retired at 11.30 P.M. and slept nearly the whole night. The spray was not again used, nor was there any occasion for it.

The next day the only evidences of any past trouble were a very slight, scarcely noticeable hoarseness, and an occasional cough, neither of which existed when I called twenty-four hours later.

The only objections to the use of cocaine in such cases of which I am aware are, first, the possibility of the patient swallowing a poisonous dose, or second, if the spray were left in the hands of a person not capable of using it intelligently, or at such times only, and in such quantities only, as are necessary, the possibility of the absorption of such quantity as might work badly with a patient such as mine, for instance, a nervous, sensitive lady, very susceptible to drugs of all kinds, and poor in health at her best.

INCUBATION PERIOD OF CHICKEN-POX DELAYED BY MEASLES, AND PAROTITIS FOLLOWING CHICKEN-POX.

By HOBART CHEESMAN, M.D.,

NEW YORK.

In reading the case of mumps *versus* measles, by Dr. Beverly Robinson, in the Medical Record of June 8, 1895, I was reminded of a case which occurred in my own family several years ago, in which the period of incubation of chicken-pox was protracted by an exposure and attack of measles taking place between the time of exposure and that of the attack in the former disease. An elder sister, about ten years of age, while attending school, was attacked by chicken-pox. A younger sister, about six years of age, not attending school, and at home, was exposed daily to the chicken-pox during the time the elder sister was down with it. While the latter was convalescing she was attacked with measles, which she must have also contracted while at school, before the chicken-pox broke out. The younger sister was exposed to the measles also, while the elder was sick with it. About twelve or fourteen days subsequent to the breaking out of the measles in the elder, the younger sister was attacked with measles. This was eighteen or twenty days after she had been first exposed to chicken-pox. The measles proved quite a sharp attack, but ran the usual course. About the time the last trace of the eruption was disappearing, an eruption of chicken-pox came out. This appearance was from twenty-seven to thirty days subsequent to the beginning of the attack of chicken-pox in the elder sister, when the younger was first exposed to it, a longer time than the longest period of incubation of this disease mentioned in text-books.

Another case, but of a different nature, and which happened recently in my practice, may be of interest because of its rarity. There are three boys in the family in which the case occurred, aged respectively thirteen, nine, and five years. The first and second attend school, the younger stays at home. While attending school, the second boy was attacked with chicken-pox. About nine or ten days thereafter, the youngest boy came down with it, as did also the eldest a few days later. The disease ran in each case the ordinary course. About a week after the attack began in the youngest boy and after he had nearly recovered, an inflammation in the left parotid gland developed, which resembled every way a mild case of mumps. The shape and site of the swelling were exactly the same, there was moderate tenderness, and the skin over it was perceptibly reddened. The pulse-rate was increased, and the temperature went up to 100° F. for about thirty-six hours. A few drops of lemon-juice and water

put in the mouth of the patient caused him to wince and clap his hand over the swollen gland. The swelling subsided in three or four days. The second boy was in the same room all this time with this patient, but did not contract mumps, neither did the eldest, who was also exposed. The latter, so far as I could learn, had never had mumps, although he possibly had it before I knew him; but the second boy I know has never had the disease, for I have attended him since his birth; and besides, there had been no possibility of exposure to mumps for at least three weeks previous to the development of the parotitis. Although this is a sequel, mentioned as not very infrequent, to the exanthematous diseases in children, I do not find it referred to in this relation in connection particularly with varicella, nor have I ever seen it before in connection with this particular disease, nor has anyone whom I have questioned regarding the matter. Presumably, therefore, it is a somewhat rare condition.

328 West Fifty-seventh Street.

EPISTAXIS.

BY JOHN B. RICHARDSON, M.D.,

Louisville, Ky.

I PRESUME no apology is necessary for reporting an extreme case of the above nature, with treatment employed.

May 2, 1895, was hurriedly summoned to attend Miss F——, aged thirty-eight years, suffering with violent nose-bleeding. Nearly four years since, waited upon this same patient, when it required ten days or more to entirely relieve her, so profuse and troublesome was the hemorrhage.

She came of a family of "bleeders," her mother, maternal uncle, and her brother having on several occasions had bleedings from the nose difficult to control. Nothing specific in family history discoverable, upon critical questioning, along that line.

Cleansing the nasal cavity as quickly as possible, I applied a small piece of absorbent cotton, which had well rubbed into its meshes finely pulverized alum, to the bleeding point, using firm pressure for several minutes, hoping thereby to effect the formation of a clot, and thus check the bleeding. This was accomplished, but only lasted for a few hours. Two days elapsed, when a message reached me she was bleeding to death. I found her pulseless at the wrist, with sighing respirations, and a stream of blood (arterial) running from her left nostril and down pharynx, being swallowed, and a moment afterward she fainted. Upon returning to consciousness, she vomited many ounces of blood.

Employing reflected light, the nasal cavity was cleared of blood-clots and flowing blood; the eroded and broken wall of the vessel was found to be located at the junction of the floor of the right nares and septum of the nose, three-fourths of an inch posterior to its external orifice.

Preparing a piece of absorbent cotton which, when well compressed, would be somewhat larger than would be received by the posterior nasal orifice, I secured to its centre a double aseptic ized waxed cord, also a second single cord for the subsequent removal. I placed this posterior plug in position by means of Bellocq's cannula. I then moistened a small piece of absorbent cotton with the iron solution and passed it in the clasp of an ordinary pair of nasal forceps to the ruptured side of the bleeding vessel, and retained it there for some minutes—upon this procedure I wish to lay stress—placing other small compressed pledgets upon the first one applied (after the manner, when properly done, we proceed in tamponing the vaginal canal in cases of uterine hemorrhage), finally introducing the larger anterior plug, pressing it compactly and well filling the anterior portion of the nasal cavity with it, and securing in position by tying over it in single-bow knot the double cord passing out of nostril from posterior plug.

Prior to using small pieces (as last described), I was troubled, at the end of twelve or fifteen hours after each replugging, with slight recurring bleedings caused doubtless by failure in clot-forming at the immediate point of hemorrhage: these recurring bleedings, slight at first, continued and increased until it became necessary to remove both anterior and posterior plugs and apply others.

General treatment consisted of hypodermic injections of ergotole pro re nata: cooling and acid drinks; nutritious fluid food in small quantities at short intervals; with perfect quietude of body and mind; for my patient was almost exsanguinated.

Twelve hours later oozing of blood began from the left nostril, the blood finding its way between the posterior plug and nasal septum, thence into the left nasal cavity and out of the left nostril; also downward through the pharynx, large quantities of which were swallowed. This increased very rapidly several times during the following week, necessitating replugging. These hemorrhages seemed to come in regular cycles of from twelve to fifteen hours' intervals, the blood-pressure requisite to produce them seemingly requiring that length of time to be re-established. These oft-repeated rebellious hemorrhages, notwithstanding the most careful, deliberate, and painstaking manner in which both anterior and posterior plugs were applied, recalled to mind a formula I had administered in many cases of intractable hæmoptyses and metrorrhagiæ, the *modus operandi* of whose action I have never perfectly understood, and yet know it to be very effective. This I prescribed, and after its employment in conjunction with "plugging" there was no further hemorrhage. The formula is as follows:

R.	Hydrarg. bichlorid.	gr. j
	Acid. muriat. dil.	ʒ ij.
	Tr. cannabis ind.	♏ ij.
	F. E. ergotæ	♏ iij.
	Syp. simp.	♏ j.
	Inf. quassiæ	ʒ vijss.
M.	Ft. and sol. Sig.: Tablespoonful in water t.i.d.	

Before concluding I desire to mention a practical point, viz.: Prior to the final removal of the posterior plug from its position, secure a second double (fresh) cord to the one attached to the posterior nasal plug (from which it passes through the nasal cavity, out through the anterior orifice); as the old one is removed let the new double cord trail after it, thereby placing it in the position for immediate use should occasion again arise for further plugging, thus obviating the need for a second introduction of Bellocq's cannula; which latter cannot be accomplished without attendant danger of disturbing the "temporary clot." More than six weeks have now elapsed since the removal of what I term the "guard-cord," and patient has had no evidence of a return of her bleeding, and has almost regained perfect health and strength.

Foreign Medical Students in France.—French medical students have been crying out against "the invasion of foreign students," and the *Progrès Médical*, one of the most sensible and fair-minded medical journals of Paris, has undertaken to show that there is nothing to fear from that source. In 1894, for example, out of 249 hospital internes, only 14 were foreigners. "In face of the efforts made by other countries to attract the largest number possible of foreign students, the complaints and recrimination in France on the subject are astonishing," says the editor, Dr. Bourneville. "Indeed, to accord the right to students of all nationalities to study in the French universities on the same terms as Frenchmen, and to take part in competitive examinations, will do more good than any number of military expeditions."

TONSILLAR TUBERCULOSIS.

ALTHOUGH the functions of that collection of lymphoid tissue encircling the oro-pharynx, and called at different points the pharyngeal, faucial, or lingual tonsils, are still in dispute, it is well known that it is a site of infection from various pathogenic germs. The different catarrhal affections to which it is subject impair the integrity of its epithelial investment, and though phagocytosis may occur at these points to some extent, the resistant force is frequently overcome by the invasion from without. Of recent years much attention has been paid to the question as to whether the various tonsillar areas are not the channels through which the tubercle bacillus may gain entrance to the system. Where this has seemed to occur, it is believed that some one of the microbes of suppuration has carried the outpost, and opened up a way of entrance for the bacillus itself.

Tuberculosis of the pharynx and naso-pharynx may appear in the course of an acute or chronic pulmonary tuberculosis with characteristic local lesions and symptoms. Dieulafoy has recently called attention[1] to another form of the localized affection, which he believes to be very common. It presents neither granulations nor ulcerations, and it is not, as a rule, at all painful. Functional troubles may arise at times, but they are so slight as not to suggest the real cause; but the condition should be recognized, as it may be the starting-point of a general systemic infection.

This latent tuberculosis has its favorite seat in the adenoid (more properly lymphoid) tissue of the naso-pharynx. It manifests itself most obviously as a mere enlargement of this tissue, without at first sight any peculiar characteristics. This form Dieulafoy styles "latent" tuberculosis of the tonsils. To put it in another way, he believes that if tonsils removed from either the pharynx, fauces, or tongue are submitted to careful examination, they will be found to contain tubercular foci far more commonly than has generally been supposed. In fact, out of 61 examinations of supposed simple hypertrophic tonsillar tissue, he found the bacillus in 8 cases. Out of 35 cases of naso-pharyngeal adenoids, the bacillus was present in 7. In the first group, bits of tissue were introduced under the skin of guinea-pigs, and all succumbed: six with local tubercular nodule and general tuberculosis; 2 without local deposit, but with pulmonary lesions; 49 without any appreciable lesion or without an autopsy having been made; and 4 with the lesions of septicæmia. In the second group 3 died with nodule and general tuberculosis; 4 with tuberculosis without nodule; 3 with septicæmia; and 25 without apparent lesions.

The patients from whom the tonsillar tissue was removed were nearly all children under ten years. None of them presented any of the local or general evidences of tubercular infection. Dieulafoy supposes that they all possessed what, for lack of a more exact term, we call the tubercular "predisposition," and that this lymphatic soil was first inoculated by some of the bacilli which are found at times in probably every healthy nose. Again, the experiments of Chauveau, Orth, Baumgarten, and Cadéac conclusively prove that the swallowing of material containing tubercle bacilli can infect both the faucial and pharyngeal tonsils. Dieulafoy does not believe that the penetration of the bacillus into the tissue requires a preceding erosion or wound. This statement, however, cannot be supported in the light of our most recent knowledge, as hereinbefore suggested.

The inoculation of the lymphoid tissue by the bacillus is followed by a functional super-activity—a multiplication of lymphoid cells which gives to the tonsillar masses a considerable volume. This is the first step of the process. Later, after months or years, the phagocytic action fortunately predominates in many instances, and fibrosis ensues. The tissue lessens in volume, and here, as in many cases of tuberculosis, a cure or cessation of the process is accomplished without any systemic infection. In other cases this happy result does not follow, and the second stage is manifested in the appearance of submaxillary and cervical glandular enlargements. The lymphatic channels are probably the route through which the infection travels. The course of this extension is always anatomically downward. The ganglionic tuberculosis may be arrested, but the danger is that the advance-guard of the enemy will sooner or later appear before the pulmonary outposts. Even here all is not lost, for the pulmonary structure can defend itself to a certain extent, and it responds, according to Dieulafoy's view, to the bacillary attack by hemorrhage, which he terms one of defense (*hémoptysie de défense*).

The foregoing views in general are not essentially new. Over a year ago Lermoyez reported two cases in which the removal of adenoid vegetation seemed to be the signal for a general tubercular invasion. In the second case, that of a child of six years, a second operation was necessary, and the tissue then removed was examined and bacilli found.

A therapeutic suggestion in these cases is afforded by the experience of Fyffe,[1] who injected the sputum of a tuberculous patient into guinea-pigs. The more creosote the patient took, the less virulent the sputa seemed to become. Finally creosote was injected into the animals before they were inoculated with bacilli, and it seemed to greatly hinder the progress of the disease. In cases of tubercular adenoid disease it might be that, if creosote were given early, it would greatly lessen the probability of the affection going beyond the first stage.

[1] Lancet, September 22, 1894.

DEATH IN THE AURAL TYMPANUM.

Every now and then the publicity given to the death of some prominent person from inflammation of the drum of the ear calls attention to the subject. Much valuable time is often lost in the futile efforts made for its relief at the beginning, not to mention any bad effects of meddlesome treatment afterward. Cases of this kind are by no means rare, and it may be said of most of them that recovery would not have been impossible but for their neglect or unwise treatment.

The danger in these cases lies either in the extension of the morbid process arising in the tympanum to the adjacent cavities of the mastoid, with which a free communication exists, or to intracranial regions by means of communicating vessels. Most suppurating middle-ear affections will get well spontaneously if the simple rules of surgical drainage be observed. But, as Dr. Sexton remarked before the Practitioners' Society, in commenting on a paper on sinus empyema by Dr. Abbe, and reported elsewhere in the present issue of the Medical Record, it is generally found, in these and other fatal cases of ear disease, that we have to deal with a run-down subject, and that the patient has been over-zealously treated and without the observance of ordinary aseptic precautions. Thus a mild case of otitis media, by the unskilful use of an unclean knife carrying infection into the drum and setting up profuse suppuration there, or by infection from syringing the ear with foul water, may speedily be converted into a grave one. Or, the pernicious practice of inflating the drum in such cases with the air-bag may convey septic secretions from the naso-pharynx to the ear, and also distribute the morbid contents of the drum to various regions of the pneumatic system of the middle ear.

The profession once had a precept, "Let the ear alone," which has been, wisely or unwisely, abandoned for the sometimes excessive meddlesomeness of enthusiastic aurists. Indeed, it may well be questioned if the former method was not attended with less evil than the latter.

THE STATE LUNACY COMMISSION.

The State Lunacy Commission is having its innings in its controversy with the medical superintendents of this State. In a recent report of the committee of the State Legislature on the work of the State Lunacy Commission, and upon the general condition of the State Asylums for the Insane, a large part of the contents is devoted to showing that the salaries of the superintendents of the State hospitals are too large, and that the gentlemen who receive these salaries live a joyous and sybaritic life, rolling about in carriages at the expense of the State, living in houses whose annual rental is worth $2,000, and altogether wasting the money of the State in a manner which is most shocking. We find it also stated in the report that the function of the manager of the State hospital is not a very important one, and that it should be made, if anything, still more restricted, until the work done by these managers becomes more and more perfunctory. The result thus aimed at will be to place the asylums in the direct control of the superintendents, who are so much overpaid, under the special direction of the State Lunacy Commission. This commission, the report adds, has done a great deal of good in the way of saving money for the State; and the legislative committee, on the whole, seems to be very much pleased.

We have, at other times, expressed our views upon this subject. There can be no doubt about the fact that the commission has done excellent work; but from a medical stand-point it seems as though they cared very little about securing more efficient work, or promoting scientific work in any way. The main object of the commission seems to have been to reduce the expenses and to get all the State hospitals in a very useful, machine-like condition.

BLOOD PLATELETS IN FUNCTIONAL NERVOUS DISEASES.

It seems impossible for persons, even the most seriously minded, to undertake the study of the blood without discovering something new and extraordinary, which no one has seen before and which few others are ever persuaded to see. The history of the anatomy and pathology of the blood is a history of all kinds of now exploded discoveries and theories, from the fourth corpuscle to the yeast germs. We note that a St. Louis physician, Dr. Bremer, has also been investigating the state of the blood in several hundred cases of neurasthenia. The result of his investigations, of course, has been to discover certain changes by which he is able to diagnosticate cases of neurasthenia from a blood examination alone. Dr. Bremer's diagnostic sign is, we believe, the enormous production of blood "platelets." Naturally it is Dr. Bremer's view that neurasthenia is not only a nervous affection, but also a disease of the blood. Curiously enough, Dr. Bremer finds that, despite this pathology, bromides, which are blood-destroyers, are the best things for neurasthenia, the salutary effects, he thinks, being perhaps due to the production of sleep.

Half a Million for a Brooklyn Dispensary.—The memory of the late Henry D. Polhemus is to be perpetuated by the erection of a dispensary building in connection with the Long Island College Hospital in Brooklyn. It will be the gift of Mr. Polhemus's widow, who has purchased three city lots for the purpose. The building will be five stories high, and will be known as the Polhemus Memorial Dispensary. The estimated cost of the structure, with its furnishings, is $250,000, and in addition to this Mrs. Polhemus will present the dispensary with an endowment fund of $250,000 for its maintenance.—*British Medical and Surgical Journal.*

A Gentleman who has Lately Become an Inebriate asks in *The Lancet* for a home. He is eighty years of age and has an income of £60 a year.

Baroness Possauer, of Vienna, has presented a petition to the Austrian Government, praying that women, if properly qualified, be allowed to practise medicine and surgery in that country.

News of the Week.

The Bicycle and Medical Practice.—The use of the bicycle has expanded and developed from a salutary athletic exercise into a great social obsession. It has seized upon every class of society, both sexes, all ages, and every condition of life. It is taken up by the well because it makes them feel better, by the invalid because it makes them feel well, by tired people because it rests them, and by the rested because it makes them feel tired. The fat ride to get thin and the thin to get fat. It has displaced the horse, and in women has, in a measure, replaced the uterus. It has made the simple and ancient custom of walking most unpopular; it has cut down the function of the steam-car, and competes successfully with the suburban trolley. The doctors have taken it up and expressed their approval of it, and we are far from saying a word in opposition. The bicycle has come to stay, though not with quite the omnipresent activity which it now enjoys. Already we notice grave and reverend seigniors in our profession riding along the cobble-stones in their golf suits instead of lying comfortably back in their victorias. Time that used to be spent in serious scientific pursuits at the hospital, in the laboratory, and at the desk is now shortened in order to enjoy a ride up the Boulevard. The bicycle has cut down the scientific activity of the New York profession at least fifty per cent. already.—*The Post-Graduate.*

Dr. John T. Nagle, Register of Vital Statistics of the New York City Board of Health, has been retired upon his own application. Dr. Nagle was appointed a health inspector in 1869, and has been a most efficient officer of the department. He is succeeded by Dr. Roger S. Tracy, himself a member of the Health Department for more than a quarter of a century.

Professor Johann Mikulicz, of Breslau, has been called to the University of Bonn, to take the chair of surgery formerly held by Professor Trendelenburg.

Dr. Charles C. Hendricks, of Hoboken, has been appointed Health Inspector of Hudson County, N. J., to succeed the late Dr. Saltonstall.

The U. S. Custom-House in New York is reported to be in a very dangerous sanitary condition, with leaking drain-pipes and defective ventilation. The building is also reported to be structurally unsafe, and in danger of collapsing. The Treasury Department has been repeatedly notified of these defects in the Custom-house, but nothing has yet been done to protect the lives and health of the government clerks.

A Righteous Verdict in a Libel Suit.—Drs. A. E. Davis and B. F. Parrish, of this city, secured verdicts on July 15th against the *National Police Gazette*, each for $25,000, for a libel published two and a half years ago. This was the same libel for which the plaintiffs secured verdicts of $2,500 against the *Sun* Publishing Company, about two months ago. We renew our congratulations to Drs. Davis and Parrish, who have so effectively punished their slanderers.

The Late Dr. Stephen E. Fuller.—At a meeting of the Kings County (N. Y.) Medical Association, held June 11, 1895, the following resolution was adopted:

Whereas, Dr. Stephen Edward Fuller, an old and highly esteemed member of this Association, has been removed from our membership by death;

Resolved, That this Association, while bowing to the inevitable and mourning its own great loss, tender to the widow and family our sincere sympathy and heartfelt condolence in their affliction.

GEORGE A. OSTRANDER, M.D.,
THOMAS M. ROCHESTER, M.D.,
Committee.

Obituary Notes.—DR. JAMES CALEB JACKSON, who nearly forty years ago founded the Jackson Sanitarium at Dansville, N. Y., died at his home in that town recently, in his eighty-fifth year. Dr. Jackson was an active co-worker with Lloyd Garrison and other anti-slavery agitators, and edited several newspapers at different times in support of his political beliefs.—DR. A. H. BURBANK, of Yarmouth, Me., died on June 27th. He had practised in Yarmouth for nearly fifty years.

The Czarewich has Consumption.—It is announced that Dr. Leyden, of Berlin, and Professor Nothnagel, of Vienna, have been called to see what can be done for the Czarewich, who is said to be suffering from phthisis in an advanced stage.

Professor Ludwig Traube.—A memorial bust of the celebrated physiologist Traube has recently been erected in Berlin.

The Value of a Good Name.—The *Berliner klinische Wochenschrift* says that if Dr. A. Jacobi's name were not attached, one would not believe in the statement that he had had a patient with a temperature of 65° C. Such a case was reported, however, by Professor Jacobi at a meeting of the Association of American Physicians this year. In the discussion Professor Welch reported another case of 77° C., or 171° F. Professor Welch has also a good name, but it would not stand many more degrees centigrade.

A Hospital for the Colored Race.—A new hospital organization has been incorporated in this city under the name of the McDonough Memorial Hospital Association. The new hospital will be managed mainly by colored persons. It will be on the west side in New York, at some point between Twenty-third and Seventy-second Streets, within some district largely populated by colored people. A site is now being looked for, and the work of erecting a suitable building will be begun as soon as one is selected. It is expected to maintain the hospital by voluntary contributions, and already assurances of substantial contributions have been made—one wealthy friend of one of the incorporators having promised to fit up the dispensary department of the new hospital and another the department of surgery.

Dr. Frederick W. Smith, of Syracuse, has been appointed by Governor Morton to succeed Dr. Florence O. Donohue as a member of the State Board of Health.

Dr. Thomas S. Hagan, assistant physician at Hart's Island, was found dead in his room on Wednesday

morning, with his throat cut. There were deep gashes in his throat and on his left wrist and a number of slighter wounds and contusions on other parts of his body. No knife was found in his room, and it is thought one of the lunatics on the island may have committed the fatal assault.

Dr. John B. Murphy, of Chicago, was tendered a reception at the residence of Dr. Thomas H. Manley, of this city, on Friday evening of last week. He sailed for Europe the following morning.

Buffalo Bill and the Sick Children.—During the late visit of Buffalo Bill and his "show" to this city the grounds upon which the show was held were very near the Children's Hospital. The music of the cowboy band, the sound of the gun-shots in the attack on the settler's cabin, etc., attracted the children's attention, and when they were told that the noises were made by Indians their grief at their confinement increased in proportion to their desire to see a real live Indian. One of them asked the visiting surgeon if there was no way in which this could be brought about, and the surgeon suggested that he write a letter to Buffalo Bill and ask him. The boy wrote the following letter:

"DEAR MR. BUFFALO BILL: We are a lot of little children lying on our backs in the hospital and we cannot move. We want to see an Indian very much. We have *never* seen one in our lives and cannot get out. Will you please send us one, so that we can see him?"

Buffalo Bill was evidently touched by this appeal, for presently six Indian braves, a squaw, and a papoose visited the hospital and walked about the wards in full regalia, greatly to the delight of the children. The Indians were about to execute a war-dance for the children in one of the wards, when the chief demurred on account of the waxed floor, which he thought was too slippery for a proper performance of the ceremony. —*Boston Medical and Surgical Journal.*

True.—That very progressive medical journal, the MEDICAL RECORD, of New York City, is about to increase still further its facilities by adding to the number of its pages. Dr. Shrady and his staff have succeeded in bringing up the small journal which was started many years ago to be the leading medical journal of the world.—*Maryland Medical Journal.*

Prejudice and Exaggeration.—About a month ago our New York correspondent related particulars of two cases of diphtheria, which terminated fatally after the use of antitoxin. Most of our readers must have felt that the cases, as given, were not conclusive in respect to the allegation that the injections were responsible for the result, in spite of the statement of the physician administering them, who is reported to have said that some mistake must have been made in the preparation or bottling of the remedy. Indeed, in one of these cases it is clear that the patient was obviously dying from diphtheria itself when resort was had to antitoxin. The record has, however, been seized upon by Mr. Ernest Bell, who has disseminated it broadcast in a letter which has been inserted in a large number of provincial papers, and this writer has the effrontery to say that "similar fatalities" are being heard of "from all sides." We venture to affirm that there is no justification at all for such a sweeping assertion, but, on the contrary, that already there is abundant proof that this remedy has had a surprising influence in diminishing the mortality from diphtheria. The attempt to excite prejudice by such exaggerated statements cannot be too strongly reprobated, and we can only express astonishment that they should have been accepted without demur by those who are responsible for the guidance of public opinion.—*The Lancet.*

Cholera in Japan.—It has been reported that cholera was raging in many parts of Japan, but advices received by the Marine Hospital Service show that these reports were exaggerated. There were but fifteen cases at Osaka and Hiogo up to June 15th, and none at all at Nagasaki and Yokohama.

Yellow Fever in Brazil.—The captain of a vessel recently arrived from Santos says that when he left that city yellow fever was raging. According to his possibly somewhat overdrawn description, men were dropping dead in the streets, dying by scores in the city and on the vessels in port. Some of the vessels had their flags at half-mast day after day for weeks, as man after man of their crews succumbed to the scourge. The death-boat was rowed about the harbor day and night, from vessel to vessel, collecting the dead and taking the bodies ashore for burial. Some of the vessels had only one or two men left of their entire crew, and many of them were unable to get away owing to lack of men. As we have before suggested, Dr. Domingo Freire has here an opportunity to demonstrate the worth of his preventive inoculations of yellow fever that, believing as he does in their efficacy, it seems little short of madness to neglect.

Erythropsia (Red Sight) of Ten Minutes' Duration.—Dr. Hilbert, of Gensberg (*Memorabilien*), reports the case of a woman sixty-three years of age, quite neurasthenic, who became exceedingly alarmed by the announcement of some unpleasant news. She suddenly saw everything red, and objects continued to have uniformly the color of blood for at least ten minutes. The symptom then gradually disappeared. A few other cases of erythropsia or red sight have been reported by Borel and others. The symptom is a very curious one, and when complete is due, it is believed by Hilbert, to a central disturbance.

Leprosy is Increasing in Iceland in an alarming manner, according to the Jesuit missionary, Father Sveinsson. Last year a Danish physician, sent by the government, examined one-third of the island and found one hundred and forty-one lepers.

On the Occasion of Prince Bismarck's Birthday the German Emperor conferred the title of "Medical Privy Councillor" on the statesman's physician, Dr. Schweninger, of Berlin.

Wholesale Ice-cream Poisoning.—In Odessa recently over two hundred persons were poisoned from eating ice-cream. Seven of the number died. The authorities suspected that the poisoning was intentional and made numerous arrests, but could not substantiate the charges brought, and finally let the matter drop, and attributed the disaster to tyrotoxicon.

Reviews and Notices.

THE PHYSICIANS' GERMAN VADE-MECUM. A Manual for Medical Practitioners for Use in the Treatment of German Patients. By RICHARD S. ROSENTHAL. Vols. I. and II. Chicago: The Rosenthal Publishing Co.

THE popularity of this work is shown by the fact of its having attained its eleventh edition. It is particularly adapted to those medical men who have but a superficial knowledge of conversational German and a very limited acquaintance with medical technicalities in German. To one who is unacquainted with the language the book is of little value, in fact, would be dangerous to use, for mistakes might happen which would be very misleading to the physician.

FONCTIONNEMENT DE LA MAISON D'ACCOUCHEMENT-BAUDELOCQUE. Clinique de la Faculté dirigée par le PROFESSEUR ADOLPHE PINARD. Pp. 100. Paris: G. Steinheil. 1895.

PROFESSOR PINARD, since 1882, when he first was connected with the Maternity de Lariboisière, and afterward with the Clinique Baudelocque, has published each year the results of his service. Each year he says he has proved a constant diminution of deaths of the mothers and the children. Of the two thousand one hundred and thirty-seven women at the Clinique Baudelocque in 1894, the total mortality numbered only seven. He attributes his success not so much to the methods employed as to the fact that he does not change his interns, his assistants, or his nurses. The tables and classifications of the more than two thousand cases will prove of great interest to the obstetricians, and are models of accurate and careful scientific investigation.

THE DISEASES OF PERSONALITY. By PROFESSOR TH. RIBOT. Pp. 163. Chicago: The Open Court Publishing Co. 1895.

THE second revised edition of the authorized translation of Professor Ribot's interesting psychological study in diseases of the personality will find great favor with American readers. The work was first published in 1884, at which time the ideas of the physical basis of the mind had not been so widely accepted as at present.

In the preface to the last French edition in 1891, after remarking on the wide study of the subject of disorders and alterations of the personality which has taken place since he first wrote, he comments on the experimentations made with hypnotism, styling them provoked alterations of the personality; the others are spontaneous alterations. While recognizing the value of investigation of the provoked and artificial disorders, he believes that the spontaneous alterations still remain the most solid data for the study of morbid manifestations of personality.

Those who have not already read the book in the original will find a most excellent translation of this valuable and instructive psychological work.

THE DISEASES AND DEFORMITIES OF THE FŒTUS. An Attempt Toward a System of Anti-Natal Pathology. By J. W. BALLANTYNE, M.D., F.R.C.P.E., F.R.S.E., Lecturer on Midwifery and Gynecology, etc., School of Medicine, Edinburgh. With plates. Vol. II.

CONGENITAL DISEASES OF THE SUBCUTANEOUS TISSUE AND SKIN. Pp. 264. Edinburgh: Oliver & Boyd. 1895.

IT is two and a half years since the first volume of this series was published. The delay has been occasioned by the researches necessary to the obscure subject. The present work is an elaborate description of sclerema neonatorum, subcutaneous abscess, ichthyosis, and other congenital cutaneous affections.

These volumes, with the others which are to follow, will fill a place in medical literature which has not yet been worthily occupied.

ON SOME SYMPTOMS WHICH SIMULATE DISEASE OF THE PELVIC ORGANS IN WOMEN: AND THEIR TREATMENT BY ALLO-PIESTO-MYO-KINETICS (MASSAGE), AND BY AUTO-PIESTO-MYO-KINETICS SELF-MOVEMENTS OF MUSCLES UNDER PRESSURE. By A. RABAGLIATI, M.A., F.R.C.S. Ed., Honorary Gynecologist, Late Senior Honorary Surgeon Bradford Infirmary. Pp. 95. New York: William Wood & Co. 1895.

THE profession will take great interest in Dr. Rabagliati's brochure, as it deals with a class of cases which is the most puzzling to physicians, and which tax their ingenuity to the uttermost—neurasthenic women. The writer thinks that too much stress has been given to the nervous origin of these troubles, called neurasthenia; that while in some instances the nervous system is involved, in many the primary seat is in the muscles and muscle sheaths, and that also the nerve sheaths and the periosteum or bone sheaths, the joints, true and false, are also affected in these cases, which are probably of rheumatic character. He says that many times disease of the uterus and its appendages have been simulated by this trouble, even to such an extent as to have occasioned the removal of ovaries.

He regulates the diet of these patients and initiates them into a series of self-massage, the modus operandi of which is well illustrated by a series of beautiful photographs.

A TREATISE ON THE NERVOUS DISEASES OF CHILDREN FOR PHYSICIANS AND STUDENTS. By B. SACHS, M.D., Professor of Mental and Nervous Diseases in the New York Polyclinic, etc. New York: William Wood & Co., Publishers.

THE advent of a book such as the one before us shows the tendency toward specialism of medical science at the end of the nineteenth century. Within a generation ago, a text-book, or a volume devoted exclusively to nervous diseases, would have been a novelty, but to-day the requirements of the times are such that excursions into the realms of science must be done so well and thoroughly that it is beyond the capabilities of individual man to do them satisfactorily without a division of labor. That such division of labor is advantageous can be readily seen by an examination of the present treatise, which fulfils in a most satisfactory way the promptings that led to the writing of the book, which the author states in the preface to have been the making of a treatise "which would give both the physician and the student fuller information regarding these diseases than is to be obtained from text-books on pediatrics."

The book is contained in an introduction and two parts. The first fifty pages are devoted to a consideration of the modes and methods of examination which will lead most reliably to a diagnosis. By the judicious use of tables and illustrations, the author has succeeded in presenting a really massive amount of information, and that of the most useful kind, in this chapter, which, especially to the student and to one unfamiliar with the intricacies of neurology, must be of paramount importance.

Part I. is devoted to the general nervous diseases and Part II. to the organic diseases of the nervous system. The author has departed from the usual custom by presenting first the functional disorders; and we are told in the preface that he did so advisedly, not alone because they are of the greatest practical importance and constitute fully one-half of the nervous diseases observed during early years, but that several of these disorders, such as convulsions, epilepsy, and hysteria, have an important bearing on the life of the child and are so closely related to many organic nervous diseases of the nervous system that it seemed absolutely necessary to explain these functional troubles before proceeding to a discussion of structural disease. This arrangement will probably commend itself to the practitioner. It is of the utmost importance to keep in mind the intimate relationship between convulsions in children and epilepsy, and when they are presented sequentially, as they are in this book, the momentousness of this matter is impressed upon the reader. The chapters in Part I. that call for special commendation are those devoted to epilepsy, hysteria, and migraine. The pathology of epilepsy, both inferential and determined; the clinical manifestations of the disease; that extremely important matter, the management of patients afflicted with epilepsy, are put down in a masterly and convincing manner, and after reading it one feels that both the faddist and the nihilist in the treatment of epilepsy have had their claims weighed and not allowed.

In his conception of hysteria the author is inclined to take the most advanced and substantiated view of it, which places it more properly among the mental than the purely nervous disorders, using the latter term in its colloquial and every-day sense. We are sure that his positive statement, that hysteria is a rare disease, in this country, at least, not only in the adult but extremely so in children, will be concurred in by everyone who has seen much of nervous diseases, and it should go a long way toward throttling the impulse which prompts some to label every nervous manifestation which they do not understand as "hysterical" and therefore to be sneered at.

The chapters devoted to chorea and the choreiform diseases, as well as those treating of tetanus and tetany, are

characterized by the elimination of antiquated theories, by the absence of padding and the presentation of facts in a scientific and readable form. The concluding chapter of Part I. is devoted to the vasomotor and tropho neuroses, under which terms the author describes for sake of convenience, exophthalmic goitre, Raynaud's disease, myxœdema, angio-neurotic œdema, facial hemiatrophy, etc.

In Part II. the diseases of the peripheral nerves are first considered, and especially interesting is the chapter on multiple neuritis, a condition which, with the exception of the polyneuritis occurring after diphtheria, has been considered to be extremely rare in children, but which the author believes to be more often mistaken for anterior poliomyelitis than has been heretofore recognized.

The diseases of the spinal cord are introduced by a brief up-to-date consideration of the anatomy, physiology, and pathology of this part of the body, which is illustrated by a helpful colored plate taken from Flatau's recent work.

The chapters here which we would especially commend are those devoted to the hereditary or family diseases of the spinal cord and to the progressive muscular atrophies. Our conception of both of these types of disease is, at the present time, going through a very important evolutionary stage, and although it may even yet seem to the mind of the uninitiated and the casual observer that the facts concerning these two conditions are in a very chaotic state, his mind will be relieved of such erroneous ideas by the perusal of these chapters. They show a grasp of the conception of these diseases, a practical familiarity with them as they come before the physician, and a knowledge of the literature of the subjects which does credit to the author, and which will well repay the student's careful study.

The part of the book devoted to diseases of the brain is built on the same plan as the part which treats of the spinal cord. The illustrations and diagrams to illustrate these chapters have been judiciously selected and carefully executed. Meningitis and epidemic cerebro-spinal meningitis are considered from a modern pathological point of view. We are sorry the author did not present more exhaustively the subject of encephalitis, for it is hazarding a very safe prophecy to say that there is more of encephalitis Simon pure, and in combination, than books have taught us heretofore.

The infantile cerebral palsies, a subject to which Sachs has made some of the most important contributions to the literature, are particularly instructive. The same may be said of that extremely important subject, abscess of the brain and thrombosis of the intracranial sinuses, a subject on which we cannot have too much light or the reflexion of personal experience.

The closing chapters are taken up with a discussion of the common forms of diseases of the mind as seen in childhood, and the subject of idiocy and imbecility. An appendix of a few pages contains special reference to such measures as the rest cure, hydrotherapy, etc., and will, no doubt, be found useful by those who would know the detail of application of these procedures.

The mechanical part of the volume, particularly the printing and the illustrations, leaves nothing to be desired.

In conclusion, it may be said that, as a text-book of the nervous diseases of children, the book before us compares favorably with those which have already become, or are fast becoming, classics—Dana, Gowers, Oppenheim, Marie—and is a credit alike to the author, to pediatrics, and neurology.

THE SPIRIT OF COOKERY. A Popular Treatise on the History, Science, Practice, and Ethical and Medical Import of Culinary Art, with a Dictionary of Culinary Terms. By J. L. W. THUDICHUM, M.D., F.R.C.P., London. London and New York: Frederick Warne & Co. 1895.

THIS treatise contains a system of general rules on the principles of cookery, and enables the mastering of the most important culinary operations. The medical profession will find in this work many materials to assist them in dietetic disquisitions, and in the synthesis of meals to give into the hands of patients or their providers.

INDIGESTION. An Introduction to the Study of the Diseases of the Stomach. By GEORGE HERSCHELL, M.D., London. Second Edition. New York: G. P. Putnam's Sons. London: Baillière, Tindall & Cox. 1895.

THIS book is an excellent guide for the study of diseases of the stomach. The author has succeeded in being concise, clear, and practical. The treatment of hyperchlorhydria is described on page 208 as follows:

"Everything that can irritate the coats of the stomach must be interdicted. The diet must consist mainly of nitrogenous food, both because it is easiest digested, and also for the reason that it possesses the advantage of entering into combination with HCl, and thus alleviating the pain by diminishing the quantity of free acid in the stomach. Any kind of meat may be taken, even such as possesses the reputation of being difficult of digestion; but it must in all cases be plainly cooked, either roast, boiled, or grilled. Eggs and milk should form an important part of the dietary, as they are rich in albumin, and are also very effective in masking pain. Indeed, patients usually find this out for themselves, and are in the habit of taking a beaten-up egg or a glass of milk two or three hours after a meal to dull their pain. The eggs must be very lightly boiled and the milk sipped very slowly. The reason why the milk must be taken in sips is in order that it may be curdled in fine flakes, and not in a solid lump. This would certainly happen if a glassful were taken at a gulp. In these patients the milk-curdling ferment is always in excess, and consequently the curdling of the milk is very energetic. This fact will possibly explain the assertion of many sufferers from hyperchlorhydria, 'that they cannot take milk, as it always disagrees and makes them bilious.' I find that patients usually describe an attack of acute dyspepsia as 'biliousness.' Therefore, when we are told positively by a patient that milk does not agree, we must not attach too much weight to the statement and exclude it from the dietary until we have tested the effect of taking it in sips. Another point of great importance is to regulate the amount of salt taken. The quantity used in cooking and taken with the food must be reduced to a minimum, for the obvious reason that from it is derived, eventually, a large proportion of the acid of the gastric juice. All substances, such as pickles, spices, and strong sauces, that excite the secretion of gastric juice, must be absolutely avoided. As the absorption in the stomach is normal, and since there is, as a rule, no dilatation, the patient need not be restricted in his drink, and may take milk and water *ad lib.* Moreover, we must bear in mind that a certain amount of fluid is of a distinct advantage, both because by diluting the hyperacid gastric juice, it will help to diminish pain, and also because it will favor the process of peptonization, which is retarded if the stomach contents are concentrated beyond a certain point. Instead of milk, a little red or white claret may be added to the water, or kumyss may be taken if relished by the patient. All strong wines, spirits, liqueurs, tea, and coffee are to be absolutely avoided. As the object of treatment is to secure as much functional rest for the stomach as possible, only three meals a day should be taken, and nothing whatever between them, however much the patient may be tempted to do so to relieve his pain."

CONSIDÉRATIONS SUR LES RUPTURES DE L'UTÉRUS ET DU VAGIN PENDANT L'ACCOUCHEMENT. Extrait du Mémoire présenté au Concours de Médecine en Chef au Service de Gynécologie par le DOCTEUR C. I. ANDRONESCO, Médecin Adjoint à la Maternité de Bucharest (Roumanie). Imprimerie de l'Indépendence Roumaine. 1895.

THIRTY-FIVE cases of this fortunately rare occurrence have been brought together by the writer. He emphasizes the difficulty of determining whether the peritoneum, which is incredibly tough and unyielding in such cases, has been torn through in the escape of the child into the abdominal cavity. Where such is the case laparotomy is by far the best method of treatment. Laparotomy is indicated also where there is hemorrhage which cannot be controlled. In cases where the parts are irregularly torn and the rupture so extensive as to render the repair of the uterus impossible, Porro's operation should be resorted to.

UNTERSUCHUNGEN ÜBER DIE RESPIRATION UND CIRCULATION, bei Aenderung des Druckes und des Sauerstoffgehaltes der Luft. Von DR. A LOEWY. Berlin: Verlag von August Hirschwald. 1895.

THIS monograph contains an extensive experimental study on the conditions of respiration under different atmospheric pressure. Most of the experiments have been done in the pneumatic cabinet of the Jewish Hospital in Berlin. If the atmospheric pressure was gradually decreased (not suddenly) it could be done so until it was reduced to half the figure without any bad effects to the person breathing therein. There appeared only at times subjective complaints of a nervous nature, slight dizziness, tired feeling, and uncontrollable sleepy sensation. But even these symptoms could be relieved by exercise. The author comes to many valuable conclusions, of which a very important one

is that the respiratory exchange of gas in the lungs is in a high degree independent from the composition of the inhaled air.

BÄDER-ALMANACH. Mittheilungen der Bäder, Luftkurorte und Heilanstalten in Deutschland, Oesterreich, der Schweiz und den angrenzenden Gebieten, für Aerzte und Heilbedürftige. Sechste Ausgabe, mit Karte der Bäder, Kurorte und Heilanstalten. Berlin: Druck und Verlag von Rudolf Mosse.

THIS book contains a complete description of the numerous watering-places of Europe. It states the curative effect of the various waters and bathing establishments. It also gives the names of the resident physicians and the prices of the hotels.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, May 3, 1895.

SAMUEL SEXTON, M.D., PRESIDENT, PRO TEM.

Large Chancre of Lip; Disappearance under Mercurial Treatment.—DR. ROBERT ABBE first presented a patient illustrating recovery from sinus pyæmia, the history of which was read later, and then presented the woman shown at the meeting of February 1st, with a large chancre of the lip as seen in the photograph. The tumor had disappeared almost entirely under mercurial inunctions continued for three months, a drachm being used twice a day, while an eighth of a grain of biniodide of mercury was given internally three times a day. There had been no ptyalism, and the patient was in good health. Her husband, to whom she had been married six weeks before Dr. Abbe saw her, had mucous patches on his lips. She had been under treatment three weeks for supposed cancer by another physician, who leeched and lanced it, and then sent her to the Cancer Hospital to have the tumor removed. At that time there was a macular rash on the body. The interest of the case related to the very large size of the chancre, rather than to its situation, which was somewhat rare.

Phthisis Following Chancre.—DR. W. H. DRAPER recalled a case of chancre of the lip which he had seen a good many years ago. Had caused it to disappear under mercurial treatment, but the patient developed disease of the lungs with all the physical signs of tuberculosis, and died within two years. One author had stated that pulmonary phthisis was a frequent consequence of syphilis.

DR. SEXTON recalled a case of chancre of the lip caused by a friend of the family taking the child up and kissing it. He asked a question which he said was not exactly pertinent to the subject, namely, whether any of the members had observed communication of gonorrhœa to the rectum.

DR. PEABODY replied that Dr. Cutter had had a case of gonorrhœa in the mouth at the New York Dispensary, and he supposed that under favorable conditions any mucous membrane might become infected.

DR. ABBE believed that gonorrhœa of the rectum was one of the things mentioned in the text-books as occasionally met with. Personally he had never seen a case.

Pregnancy Associated with Diabetes.—DR. E. L. PARTRIDGE read a paper on this subject. (See p. 109.)

Nervous Excitement and Diabetes.—DR. BEVERLEY ROBINSON said he had nothing to contribute bearing directly upon the subject of pregnancy associated with diabetes. He might mention one or two facts which had an indirect relation. For instance, the influence of the nervous system upon the amount of sugar in the urine in diabetic patients was manifest in the case of a man under his care who, when involved in business cares in the city, had about four per cent. of sugar in his urine, and none at all when in the country amusing himself on his farm. Regarding the condition of the blood of persons dying of diabetes, in one case in which he had had it examined its appearance was that of a soup, and it was extremely acid. He did not mention this as something new, for it was not, but simply as a personal experience. He thought he had warded off comatose symptoms in certain cases of diabetes by administering alkalies freely.

Too Much Dieting?—The other point to which Dr. Robinson would call attention was the need, in his opinion, of allowing diabetic patients a more liberal diet than seemed to be taught in the books. He even regarded farinaceous food as less pernicious than was generally believed. Of course it was known to increase the amount of sugar in the urine, but whether it injured the patient was a different thing. He would like to hear an opinion expressed upon that question.

A Substitute for Sugar.—DR. PEABODY said, in reply to Dr. Robinson's query, that he had noticed that patients who had been doing badly on a rigid diet frequently improved in a decided manner when given some latitude in diet. He thought each case had to be judged of by itself with reference to diet and general treatment. He had had some experience with the article sold under the name diabetin. It was sweet, and was a sugar in its physiological effects, increasing the nutrition, but it did not act like sugar in increasing the amount of sugar in the blood or urine in patients with diabetes. In other words, it supplied the patient with a form of sugar which he was able to digest and assimilate. It was obtained from the vegetable kingdom.

Diabetes May or May Not be a Serious Complication of Pregnancy.—DR. W. H. DRAPER had had but one personal experience with diabetes in pregnancy, and he could only say that in that instance no disastrous consequences followed; the woman passed through normal labor at term. He thought, however, that the question of treatment presented, as Dr. Partridge had stated, many difficultes. It seemed to him that diabetes might be a very serious complication of pregnancy, and it might not. To determine the question would be more difficult than might at first sight appear. Sugar sometimes appeared in the urine, and was called diabetes, but more properly should be called glycosuria, simply from over-indulgence in the carbo-hydrates. He thought the personal history of the patient, and the family history, would be important factors in determining the question whether this or a more serious form of diabetes existed. Sugar appearing in the urine of a pregnant woman in whose family there had been diabetes should excite apprehension.

Primipara More Liable to Nervous Influences.—DR. ANDREW H. SMITH inquired of the reader of the paper what proportion of the cases had occurred in primipara or multipara, and in married or unmarried women.

DR. PARTRIDGE replied that the impression which he had received in reading the histories of the cases was that all had occurred in married women. It had not been stated just what number of Duncan's cases had occurred in women who had previously borne children, but he thought at least two-thirds were multipara.

DR. SMITH said the point which he had in mind was whether mental influences had had anything to do with the association of diabetes and pregnancy in these cases. All knew that diabetes sometimes arose from great mental shock. Also, that protracted mental strain sometimes produced an effect similar to sudden mental shock. An unmarried woman, finding herself pregnant, would, of course, have distress of mind, and a primipara of nervous temperament would experience greater anxiety than a multipara of stolid habit. He believed that a considerable degree of glycosuria of

transient character occurred much more frequently than was generally supposed. Owing to the fact that the sugar appeared in the urine for a while and then disappeared, it was likely to be overlooked unless examinations were made regularly for a considerable period.

Codeia in Diabetes.—Dr. Robinson said he supposed most of us had little faith in the drug treatment of diabetes, yet as he had used codeia, or codeine, to a considerable extent, after it had been recommended in a paper by a member of the Society some years ago, he would like to know what might have been the experience of others with it. There was no question in his mind but what it diminished the quantity of sugar in the urine, and could be given in considerable doses for some time without apparently affecting the patient unfavorably. He had thought that, possibly, it had done the patient a good deal of good, but the final end of grave cases was always the same.

Dr. Draper replied that for many years he had been in the habit of treating grave cases of diabetes with opium, in one form or another, and of late years with codeine. He remembered a case at Roosevelt Hospital in which he had given large doses of codeine, as much as twelve grains a day, with manifest benefit. He did not think it was necessary in the milder form of the disease, and did not use it. But where diabetes did not yield to dietetic treatment and to alkalies, he thought there was no remedy equal to opium. The disease prevailed to a considerable extent in India, and it had been the practice of the people there for many years to use opium in its treatment. The drug had one advantage—namely, that it enabled these patients to do work which they were unable to do without it on account of exhaustion.

Dr. Andrew H. Smith asked Dr. Draper if there was any other drug which would replace opium, and being asked for an example, suggested small doses of antipyrine.

Dr. Draper said he thought that this and similar derivatives of coal-tar were beneficial in diabetes to a certain extent, but especially in the mild form. He had not obtained much benefit from them in the grave form.

Dr. Smith said he had entertained the theory that possibly the circulation of sugar in the blood acted as a direct irritant upon the diabetic centre in the fourth ventricle, and that treatment calculated to lessen the irritability of this centre, or to diminish the amount of sugar in the blood, would tend to break the vicious circle. The more sugar in the urine, the more irritation; the more irritation, the more sugar.

Dr. Draper. Do you think these agents tend to diminish the influence of the diabetic centre in the production of diabetes?

Dr. Smith. It seems so to me.

Sinus Pyæmia and Jugular Thrombosis.—Dr. Robert Abbe made some introductory remarks, and then read the histories of four cases of sinus pyæmia, one being that of the patient whom he had already presented, and who had recovered from sinus pyæmia after irrigation of the jugular vein and lateral sinus.

Sinus pyæmia, he said, is a very grave complication of certain conditions, being especially liable to occur in inflammations of the middle ear. This fact and the value of surgical treatment by the Ballance operation should be more widely appreciated among general practitioners. Whenever, in the course of middle-ear suppuration, the pus has reached the lateral sinus, a form of pyæmia is set up of such gravity that it has always been regarded as a fatal malady. The sinus becomes thrombosed with a septic plug, which spreads down into the jugular vein, breaks down, and the purulent matter is carried onward into the circulation. The patient experiences violent chills, septic foci form in the lungs or other parts of the body, and death takes place from some one of the phases of sepsis. Now Ballance has shown that many of these cases can be cured; for, while not a great many have been reported, yet there have been a sufficient number to prove the great value of operative interference.

The essential features of the operation consist in ligating the jugular in the neck below the infective thrombus, so as to prevent the passage of any of the purulent material entering the circulation, then opening the lateral sinus and jugular above so as to give exit to the foul, infective matter. Now it has been found that, as soon as the jugular has been tied, the chills cease. The patient, who had been having two or three violent rigors a day, has remained free, and the natural inference has been that the chills were due to the entrance of septic matter from the jugular vein into the general circulation.

Since reading Ballance's paper in 1891 I have had a good many cases of abscess of the mastoid which I have trephined and cured in that manner. Of cases involving the lateral sinus and jugular, with thrombosis of these vessels, I have had four. In one of them I did not do the Ballance operation in its complete form—that is, I did not tie the jugular, but I uncovered the lateral sinus, introduced the needle, and drawing off only clear blood, I treated the case simply as one of mastoid abscess. But the man continued to do badly, and died on the seventh day of septic pneumonia. I have always regretted not having done the complete Ballance operation in this case, for it is probable that the septic thrombus was in the upper part of the jugular, and not in the lateral sinus itself, and had I tied the jugular below and opened it above to let out the septic material the patient might have recovered.

Dr. Abbe then read the histories of his other cases.

Case I. *Sinus Pyæmia and Jugular Thrombosis; Ballance's Operation; Recovery.*—Miss G——, aged thirty-two, trained nurse. The patient was in perfect health until two weeks before the operation; she then had an acute purulent nasal discharge and consulted Dr. O. B. Douglas, who thought she had ethmoidal necrosis, as she had one-sided frontal headache with purulent discharge. This lasted ten days and was improved, though an earache had been progressing meanwhile with continued headache.

On Saturday, April 6th, perforation of the drum with discharge of pus from the left ear, occurred spontaneously. A few hours later a violent chill took place, with a temperature of 105° F. She was then seen in consultation by Drs. Douglas, Nicoll, Pomeroy, and McNutt. The mastoid area showed no pain, tenderness, redness, or œdema. Her temperature ranged from 104° to 105° F. for three days. With recurrence of chills, delirium set in, and headache continued. Hebetude increased into semi-coma.

On Tuesday, April 9th, Dr. Andrew H. Smith was consulted and advised surgical interference, and I was asked to take charge of her. When seen she was in semi-coma and could scarcely be roused to any response. Respiration shallow; pulse thready, 120; temperature, 105° F. The mastoid still showed no external change, nor was it tender on pressure. No œdema extended backward from it under the occipital line, as has been spoken of. Along the jugular vein, however, from the tip of the mastoid down the front of the sterno-mastoid muscle two thirds of the distance to the sternum, pressure gave the patient sharp pain and roused her somewhat from her hebetude. This evidence of jugular pain had been found wanting in the morning. A little tumefaction along the upper part of the same area was now noticeable.

Diagnosis.—Sinus pyæmia and jugular thrombosis; immediate operation. Assisted by Drs. A. L. Fisk, and J. E. Nicoll. The first incision to ligate the jugular about its middle, encountered several enlarged lymphatics adherent to the jugular and fixed to it by extensive periphlebitis. The vein was not readily recognized, owing to its half-flaccid and thickened walls. A hypodermic removed from it a little dirty septic

fluid. No further attempt to deal with it until the sound vein should be ligated below.

Another incision was made low down in front of the tendon of the muscle—and the common jugular readily tied between two ligatures and cut across. The mastoid process was now freely trephined and no suppuration found. The bone was unusually hard, and its cells contained only gray granulation tissue. No fœtid bone odor was present. The lateral sinus was carefully uncovered for an inch and a quarter. It seemed full and had a transmitted pulsation, but its coats were thick and inflamed. Again the hypodermic withdrew from it dirty septic fluid instead of dark blood. It was therefore incised its full length, and the upper jugular vein was now also incised for an inch and a half, and free irrigation from one to the other with sublimate solution 1 to 1,000, and then with salt solution, was done. The jugular was split down to the clotted lymph plug just above the facial vein entrance. The upper limit of the thrombosed sinus was just at the margin of the trephine opening, and a probe pressed through it let out a gush of fresh blood, which was at once checked with iodoform gauze. All the wounds were then plugged with iodoform gauze.

The patient rallied well. Temperature fell to 99° F. within two hours; pulse to 90. The mind was clear by the following morning. No further chills or bad symptoms occurred. Some difficulty in deglutition showed itself next day owing to the pain about the tonsillar region, but with stomach-tube feeding for two days she was soon free from pain.

Daily irrigation of the jugular and sinus with bichloride and peroxide of hydrogen, followed by iodoform gauze packing, resulted in rapid improvement. The vein walls of the lateral sinus and jugular sloughed away, owing to the intensity of the septic process in which they had been involved, and the space was filled with granulation.

The patient sat up on the eighteenth day, and was shown at this Society on the twenty-fifth day after operation.

Case II.—*Sinus Pyæmia and Jugular Thrombosis; Ballance's Operation; Death.*—Young woman, aged twenty. Operation, February 9, 1893, in the New York Eye and Ear Infirmary. Suppurative otitis, one year.[1]

Two weeks since had symptoms of mastoid abscess. Trephined two days ago by Dr. John L. Adams, very small quantity of pus from eburnated bone, no benefit. Subsequent chill; temperature, 102½° F.; head symptoms. Studied by Drs. Bull, Gruening, Starr, and Vought.

Diagnosis.—Cerebral abscess of temporo-sphenoidal lobe; advised operation. Symptoms: pupils even; retina, choked disk; mental lethargy; pulse slow; no external swelling; headache; no tenderness on percussion. I suspected thrombosis, but accepted diagnosis of Dr. Starr and Dr. Vought, who had been watching the case, and trephined by their invitation. Dr. Gruening also thought the rapid fluctuations of temperature and early choked disk indicated sinus thrombosis. Used a one inch trephine, one and one-fourth inch back, and one and a half inch above meatus; enlarged this backward to avoid large dural veins; opened the dura by three-fourths inch crescent, and punctured the apparently normal brain in every direction without discovering pus. Sutured the dura and closed wound. Then turned to the mastoid and exposed the lateral sinus after hard chiselling. The sinus presented thick walls, lightly pulsating and dusky. Hypodermic needle drew a half drachm of fetid plum-colored blood. I then at once cut in the middle of the neck for the jugular, and tied it at the entrance of the facial, which I also tied; I then cut open the jugular, and free venous blood came slowly from the cut end, showing that the petrosal vein had not yet been plugged. The vein was therefore again tied. The lateral sinus was split open and curetted out. It was filled with putrid clot, very foul smelling. The upper limit of the clot was at the back of the trephine opening, where a probe let out clean blood. Iodoform tamponade of the lateral sinus and jugular wounds completed the operation, which had taken about two hours.

The temperature fell from 103° F. to normal in a few hours, and for four days fluctuated between normal and 100°. On the fifth day she had great pain in her head, became comatose, rapidly failed, and died, with rapid accession of temperature, 107° F.

Autopsy showed a limited purulent meningitis covering the right half of the cerebellum—near the end of the diseased lateral sinus, where an opening had perforated from the mastoid cells and communicated also with the lateral sinus.

Case III. *Sinus Pyæmia with Jugular Thrombosis—Ballance's Operation—Septic Pneumonia—Death on the Fifth Day.*—J. C——, aged forty-three, on March 23, 1891, was taken with the ordinary symptoms of grippe, rested a few days, and resumed work, but was taken on returning home the first day with violent earache. Abscess broke through the drum and gave relief, but repeated gathering and discharge took him to an aurist. Dr. Huntington Richards enlarged the drum opening and later trephined the mastoid. Temporary relief followed. After a week or two of diminishing discharge, a violent chill occurred, accompanied by fever and followed by sweating. These were repeated daily for four days, when he was referred to me for further surgical procedure. Other bad symptoms had come also, malaise, nausea, vomiting, loss of appetite.

He was admitted to St. Luke's Hospital, May 27, 1891, with a temperature 102⅘° F. The mastoid wound was discharging a little pus. Slight swelling and great tenderness existed along the front of the sterno-mastoid muscle from the skull half way to the sternum. Slight œdema also existed behind the jaw and somewhat in the temporal fossa. His urine showed fifteen per cent. of albumin and casts.

Operation.—May 28th. The mastoid process was gnawed away and the lateral sinus uncovered. Aspiration of it by a hypodermic needle drew a little purulent fluid. The sinus wall was hard and showed thrombosis. The jugular vein was then opened in the middle of the neck, at the junction of the facial vein, where both were found to be sound. These were ligated, and the jugular cut across above the ligature. A few drops of blood escaped. The end of the vein was then stitched to the wound. A probe passed upward pressed against a slight barrier, which yielded, and two drachms of pus flowed from the vein. Irrigation from the lateral sinus now ran freely through the jugular, which had failed prior to the probe breaking up the thrombosed clot. Sublimate irrigation was then practised upward and downward, and the neck wound closed below the jugular, which opened on the neck. Iodoform gauze packing in the sinus completed the operation.

The patient had no further chills after the operation, but he did not do as well as I had hoped. Continued evidence of his profound poisoning showed in his irregular fever, in the sloughy septic look of the wound, in his bad pulmonary condition, and continuance of his septic pneumonia. He died five days after, with temperature ranging from 103° to 105° F.

Case IV. *Mastoid Pyæmia—Jugular Thrombosis* (?) *—Mastoid Trephined—Lateral Sinus Explored—Jugular not Tied—Death from Septic Pneumonia.*—F. A. W——, aged thirty-seven, formerly a healthy man, came under my care with grave septic condition from suppurative otitis. Urine showed albumin four per cent. and casts. I at once trephined the mastoid and removed stinking pus and foul necrosed bone from the attic and middle ear, with caseous matter. The lateral

[1] Case reported in detail by Dr. Adams in the Archives of Otology, vol. xxii., No. 2, 1893.

sinus was fully uncovered, and though it looked suspiciously inflamed, pure blood, free from pus corpuscles, was drawn from it by hypodermic needle. It was therefore not laid open, nor did it seem justified to ligate the jugular. Wounds irrigated and packed.

In the evening chest pains increased, and precordial friction sounds, with right apex consolidation, showed themselves. Respiration, 40; temperature, 103° F. Patient had occasional chills.

On the third day after a very hard chill occurred, with increased evidence of pleuro-pneumonia, and a small amount of fluid was aspirated from the chest. The lung symptoms increased and he died on the seventh day after operation.

My impression has always been that if I had ligated his jugular vein, I would have given him a better chance to recover, by cutting off infection from what I now believe to have been a high jugular thrombosis without consolidation of the mastoid portion of the lateral sinus.

Dr. Robinson thought a good deal of emphasis should be placed upon the fact, as illustrated by the cases reported by Dr. Abbe and others, that there might be suppuration in the jugular and lateral sinus when the symptoms over the mastoid indicated nothing. Only the other day he had felt the anxiety which physicians were constantly experiencing lest in cases of middle-ear disease mastoid complication should arise. In this particular case he had been debating whether to call an otologist or a general surgeon, for it was not certain but what either mastoid trouble or pus in the lateral sinus might be present, but fortunately the case cleared up without any form of operative interference.

Dr. Charles S. Bull thought the cases were not rare in which sinus thrombosis occurred from suppuration of the middle ear, and without the presence of mastoid symptoms. He recalled two cases which he had seen in consultation during the winter of 1893–94. They were cases of acute suppurative ear trouble, and in one all the symptoms of sinus thrombosis which Dr. Abbe had described were present, while there were no external signs of mastoid trouble. An operation was done, the mastoid was found entirely free from pus. There was sinus thrombosis, but unfortunately meningitis had already developed prior to the operation and caused the patient's death. Nearly similar symptoms were present in the second case. There were no external symptoms of mastoid trouble. He advised an operation for sinus thrombosis, but the parents would not permit it and the child died. Autopsy proved the existence of thrombosis of the lateral sinus and jugular vein. There had been, he repeated, no external evidence of mastoid trouble in these two instances. He believed such cases were not uncommon.

Dr. Robinson inquired whether under such conditions it was desirable to make an incision simply down to the periosteum over the mastoid? Would it prove of any benefit to the patient? would the appearance of the periosteum reveal anything of the condition beneath? or, if surgeons would recommend any interference whatever, would it rather be a complete operation?

Dr. C. S. Bull replied that in his opinion one should go down to the abscess, and if none were found, open the lateral sinus.

Dr. W. H. Draper mentioned a case of suppurative otitis media in a child seen this winter in which there was singular absence of pain, but very high temperature. The drum membrane showed some congestion, but not much tension, and Dr. Buck hesitated to open it, but did open it and there was a very slight discharge. The temperature continued high, 105° F., which Dr. Draper regarded as an important symptom in these cases. There was no œdema over the mastoid, and scarcely any tenderness. Dr. Buck operated and found in the antrum a noticeable amount of pus. The child did perfectly well.

He had seen a case like Dr. Abbe's at the New York Hospital the past winter. There was no marked tenderness over the mastoid, but extreme tenderness along the course of the jugular vein, and some swelling. He had the woman transferred to the surgical ward, but the surgeons did not operate and the patient died with brain symptoms. He had noticed in a recent number of *The Lancet* two cases in which Milliken, of Manchester, had done Ballance's operation successfully, one case being acute otitis, the other chronic.

Dr. A. H. Smith said he had been very much interested in the last case reported by Dr. Abbe, as it was the one which Dr. McNutt had consulted him about and they had sent to Dr. Abbe to operate. He had been impressed with the history as it had been related to him by Dr. McNutt—recurring chills, sweating, excessive pain, symptoms of brain implication—and told her that it was probably a case of thrombosis of the jugular. He saw the patient two or three hours later, and noticed at once the swelling along the line of the jugular vein—longitudinal, cylindrical, excessively tender. Being told that it had not been present that morning, he inferred that it had taken place during the day, and suggested that Dr. Abbe be requested to come at once, prepared to operate. He had been very much gratified at the result. He believed that had the operation been deferred until next morning it would have been too late to save life, as the thrombus was rapidly extending downward, and would soon have reached a point below which it would have been impossible to secure the vein.

Dr. Smith referred to the danger, in moving these patients, of causing the septic material in the vein to break down and enter the general circulation, and said he had cautioned the nurses not to move this patient until Dr. Abbe arrived.

Meddling With the Ear.—Dr. Sexton wished to give a warning to practitioners not to treat cases of acute catarrhal trouble of the ear so rudely as was often done, judging by his personal observation. It was very difficult, it was true, to desist from doing something when called to these cases, but the patient would be better off with no interference whatever than with that which was out of place. The doctor was likely, for instance, to inflate the ear with the politzer bag and drive the purulent matter, if any were present, in every direction. Violent and unnecessary syringing would convert a simple case into a grave one. To use an unclean knife to evacuate purulent or sero-purulent matter might set up a much more virulent condition.

Dr. Abbe, in closing the discussion, said: A point of interest in the case of the nurse is the fact, as it seems to me, that it was the direct result of grippe. One other case seemed also to have been the result of grippe occurring in 1891. How many more of the cases seen by different men have resulted from that, I am unable to say. The fact that Dr. Nichols and Dr. Pomeroy had examined this patient on the morning of operation for mastoid disease and found no swelling, either over the mastoid or along the jugular vein, opens up the interesting question, how rapidly perivascular inflammation and extension of thrombus may take place. For in this case the thrombus at night was found to have extended well down in the jugular. Aside from the testimony of such able men as Drs. Nichols and Pomeroy, I would have inferred in dissecting the parts that the inflammation had been present at least three days. The case shows how constantly symptoms of sinus thrombosis should be watched for during an attack of supposed mastoid disease. Chills are most important as pointing to sinus thrombosis. In a case of simple ear trouble you may have a temperature of 105° F., without meningitis and without sinus thrombosis—simply with confinement of pus. You do not take a succession of chills. If there is a succession of chills, sweating, high temperature, I believe the evidence of pyæmia is absolute, and that the pyæmia must be the result of a septic process in which

the large venous channels are suddenly and repeatedly invaded.

One can produce a temperature of 105° F. within two minutes after injecting two grains of mixed toxins of erysipelas. So I think a succession of chills in these cases means only one thing, namely, pyæmia through the venous channels. Take this in connection with tenderness along the jugular and you may discard, as necessary to your diagnosis, tenderness over the mastoid, as this is sometimes absent. Chill and tenderness together, I believe, call for operation, else it means death.

Regarding Dr. Smith's remark as to moving these patients, Ballance warns against moving them until the jugular has been tied below so that none of the thrombus may be driven into the general circulation. In one of Ballance's most brilliant cases, he first tied the jugular, then transferred the patient and operated. It has been shown that the poison does not work backward from the sinus, but infects the patient by passing down the jugular.

Replying to an interrogatory by Dr. Peabody, Dr. Abbe said the operation was an easy one when you knew how to do it.

Case of Small Aneurism Obliterating Left Bronchus by Pressure, and causing Consolidation of Left Lung, with Symptoms and Physical Signs of Empyema.—Dr. Peabody showed specimens from a man whose symptoms and physical signs were those of empyema, and whose lesion was a small aneurism obliterating left bronchus by pressure, and causing hemorrhage into the air-vesicles and interstitial pneumonia throughout the lung. The aneurism, which was about the size of an English walnut, was on the descending thoracic aorta and compressed the left primary bronchus just below its origin. It has ruptured and filled the bronchi below with blood, but no blood reached bronchus above or trachea. Sections of the lung under the microscope showed the air-vesicles filled with blood, and their walls greatly thickened throughout and filled with young cells. The lung was much tougher and firmer than in ordinary lobar pneumonia, but in other respects resembled that condition to the naked eye.

Dr. Peabody pointed out the impossibility of making an accurate diagnosis under these circumstances, the close resemblance of the case to one of empyema, both in its history and in its physical signs, and also the light that it shed upon the causation of bronchial breathing. This sign was absent, in spite of the consolidation of the lung, and its absence was explained by the occlusion of the bronchus, which prevented the transmission of the respiratory sounds from the trachea.

The history of the case was as follows: J. B——, aged fifty; Ireland; widower; harnessmaker, was admitted to the New York Hospital, March 15, 1895. His father died of hasty consumption. Last winter he had pneumonia. He is of temperate habits. Says that since his pneumonia last winter, he has not been perfectly well; denies syphilis; he has taken cold easily, and for a long time has had a dry, hacking cough, but has been strong enough to keep about his work. Two weeks ago he contracted cold, and since then has been coughing badly. He has been short of breath, and has had pain in right side of chest. He has been sweating much at night for the past three nights. There has been no loss of flesh, nor have there been any gastric or intestinal symptoms. His appetite is good; his bowels are constipated. His chief complaint is the cough.

On admission, his temperature and respiration were normal; his pulse 92. With the exception of numerous râles at both apices, crepitant, sonorous, and sibilant, a physical examination was absolutely negative in result, both as to chest and abdomen. His tongue was moist and slightly coated; his general condition was good. His urine contained a small amount of albumin, but was otherwise negative. His cough continued very distressing, and after nine days he complained of pain in the back, chiefly on the left side; and on this day it was discovered that all over the left chest posteriorly there were dulness and absence of vocal and respiratory sounds. This led to the suspicion of fluid; and an exploratory puncture withdrew a minute quantity of whitish, thick fluid, which was proved by microscopic examination to be made up of pus. His temperature rose gradually to 102° F., and from this date until his death was usually somewhat above the normal, and occasionally as high as 103° F. His pain over the left chest continued; his cough was not improved by treatment; his appetite failed, and he gradually sank and died exhausted on April 4th, at 7.40 A.M., a little less than two weeks after the development of the first thoracic signs.

Case of Thrombosis of Basilar Artery due to Arterio-Sclerosis.—Dr. Peabody also showed a case of thrombosis of the basilar artery with softening of pons and arterio-sclerosis with peri-arteritis in a woman thirty years of age.

The basilar and other arteries of the brain, particularly the small arteries, showed the lesions clearly. There was quiescent old tubercular infiltration of one apex, but no other lesion of chest or abdomen. A history of syphilis could not be obtained.

Dr. Peabody had seen and published two other cases of thrombosis of basilar artery due to arterio-sclerosis. The patient was a German woman, thirty years of age, married, the mother of several living children, the youngest being an infant six months old, who is since dead.

She was comatose on her admission to the hospital on April 1, 1895. From her friends it was learned that she had always been a healthy woman prior to her present illness. One week before her admission she had complained of numbness and tingling in the right arm with distinct impairment of its power. Two hours before her admission to the hospital coma suddenly developed. Syphilis is denied.

Her husband stated that she had been under a strain of much care and worry about her child.

Physical examination revealed rigidity and partial loss of power in right upper and lower extremities, loss of power and sensation in right side of face, dilatation of right pupil. Heart sounds were feeble, but there were no murmurs. Urine was normal. After four days her temperature rose to 101° F. It remained without much change for several days, and then steadily rose to 106° F. on April 6th, when she died.

Dr. Kinnicutt presented the photographs of a case of general lympho-sarcoma. The case had been under his observation in the wards of the Presbyterian Hospital, and an autopsy had been obtained. The first symptoms had appeared two years before the patient's death, and the glands had been attacked in the classical order—first the cervical on one side, then the axillary and inguinal groups on the same side successively; a year later the cervical glands of the opposite side had been attacked, followed by the involvement of the axillary and inguinal.

On admission to the hospital, the superficial glands throughout the body were enlarged, the anterior and posterior cervical groups enormously so, and there were the physical signs of implication of the glands in the anterior mediastinum and of the bronchial group. A large mass could also be palpated in the umbilical region, which, it was believed, represented the retro-peritoneal glands. The liver and spleen were also enlarged, the edge of the latter being palpable three inches below the costal arch.

The differential diagnosis between a lymphatic leucæmia and a general lymphadenoma was determined in favor of the latter by a study of the blood, which showed the absence of an excess of lymphocytes; a moderate leucocytosis was present.

The autopsy by Dr. Thacher confirmed the correct-

ness of the physical signs noted during life. Aside from the involvement of the superficial glands throughout the body, a large mass filled the anterior mediastinum, the bronchial glands of both lungs were greatly enlarged, and the retro-peritoneal group formed a large tumor made of numerous nodes welded together. The spleen was greatly enlarged, weighing forty-two ounces, and its normal tissue was replaced almost wholly by lymph nodes, several measuring three and a half inches in diameter.

In the lungs, several nodules were present near the periphery, in addition to the masses about the roots. Just beneath the pericardium in the heart muscle two small nodules also were found. Sections of the heart, liver, and kidney tissues showed areas of invasion of lymphoid tissue. Sections of the various nodules showed a very similar structure, essentially a round-celled sarcoma. There were, however, "many large cells, irregularly distributed, round or angular, some with many nuclei." "The nodules appeared to the naked eye to be sharply outlined, but on microscopical examination were found to have no capsule or sharp demarcation from the surrounding structures, and tissues of invaded organs were sometimes found within the tumors."

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 6, 1895.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Medical Terminology; its Etymology and Errors.—DR. P. J. MCCOURT read the paper (see p. 115).

DR. CHARLES A. LEALE opened the discussion. The subject of medical terminology, its etymology, and errors, he said, offered to the mind material for apparently unlimited work. Scientific men of all nationalities had at various times endeavored to solve the problem. At the International Congress the learned men of the profession, speaking in a great variety of languages, had utterly failed to convey their ideas to one another. Nothing caused a deeper sense of individual humiliation than for a scientific man to sit and listen to the observations of another in his own profession without being able in any way to comprehend his meaning.

There was a great difficulty in the way of ever attaining a universal language, namely, the great variety of nations, of climate, soil, and surroundings. Experience had shown that where a people having a comparatively pure language had been transplanted to a place where the surroundings were entirely different and complete isolation prevented communication, the language formerly spoken underwent a change, which in three or four generations became in large measure incomprehensible to the people of the mother country. The people of the different provinces of one great country often failed to understand one another. An example was seen in China, where the troops from different provinces could not understand even ordinary military orders when brought under one command. Dialects prevailed among the two hundred and forty thousand American Indians so that one tribe could not understand another. The language of signs, gestures, looks, came more nearly to being universal than any other among uncultured people.

With regard to the best international language for the interchange of professional thought, he still believed that English would year by year gain the ascendency, simply because of its becoming more widely diffused and being the means by which wealth could be more readily acquired. International jealousy, under the pressure of overwhelming power, faded as a mist before us. Might made right in dealing with barbarian people.

The spelling and pronunciation of words in the same language varied in different localities. One could often tell from which college a man came by his pronunciation of such words as bronchitis, cerebritis, etc. There were still other difficulties in the way of a perfect terminology, which it seemed impossible to overcome at present. If it were based on the pathology of to-day, our knowledge to-morrow might make it absolutely inaccurate. Moreover, morbid anatomy might manifest itself in different ways under different surroundings. He could not agree with the essayist in the statement that it was humiliating that the cowboys of the plains could use language which more accurately conveyed their impressions than ours did for us. Descending to the lower orders, one found the lion, the dog, the bird, giving utterance to sounds which fully conveyed their intended meaning. It was even supposed that in inanimate nature there were harmonies which defied the understanding of man. Chemical terms were supposed to be much more accurate than those in use in other branches of medicine. We were supposed in chemistry to be dealing with exact known quantities, yet it was only a few months since a new element had been discovered in our atmosphere. Thus it would be seen that there was no end to knowledge, and that being the case, the necessity would always exist for changing our etymology or terms to make that advancing knowledge comprehensible.

Dr. Leale thought the suggestions made by Dr. McCourt were well worthy the consideration of the Academy.

DR. DANIEL LEWIS spoke next. He said he would fully confess at the outset his inability to properly discuss a paper of this character. The first impression which he had received while listening to it was the great care, labor, and energy which Dr. McCourt had expended in its preparation. The importance of the question he could not, of course, question.

It seemed to Dr. Lewis that it would be impossible to adopt a terminology to-day which would apply next year in all cases. Some palpable defects could be remedied, which remedies would be permanent, but in the field of nervous diseases, of skin diseases—in fact, of all the departments of medicine—the new pathology which developed from year to year, the diversity of opinion among pathologists themselves, would make it almost impossible, it would seem, to adopt any method of treating this subject which would relieve it of the many absurdities made apparent by the reader of the paper. Yet he would like to see Dr. McCourt continue his studies in that direction. But, after all, when one went right back to the principle of the thing, it would be recognized that if language expressed an idea which we understood, it was as good language as we needed. If he knew what was meant by the term cancer, for example; if he got a clear understanding of the idea which the speaker intended to convey, that language was just as effective, just as useful, just as instructive to him as it would be if it were strictly, in its primary etymology, scientific or accurate. If we should carry out the line of investigation started by Dr. McCourt this evening and apply it in other directions, we would find our language in all departments filled with terms, words, expressions, which had their origin—we had not studied to find where, but doubtless in some term quite as irrelevant as cancer or other medical words whose etymology had been criticised in the paper.

Objects to Naming Diseases after Symptoms.—DR. W. H. THOMSON appreciated both the learning and the motives of the author. Yet the question was hardly one which we could discuss verbally—the question of reconstructing our medical terminology so that we could get rid of the faulty ideas and delusions of former generations. Medical terminology resembled very much some rocks in geology, having been formed drop by drop and preserving many fossils. But was it necessary to change or discard these terms because the ideas

which they were once intended to convey had become fossil? We had not discarded the term calico notwithstanding the fact that calico was now manufactured elsewhere than in Calicut, yet everybody knew exactly what the word meant. Dr. Thomson did not see any practical gain in changing medical terminology in the sense of the purist. We would all get at loggerheads if we attempted it.

Then should we attempt to establish a terminology for newer names based on pathology? Here we were met at once by difficulties already alluded to by Dr. Leale and Dr. Lewis. We could not get our pathology to stay good: we had not the pathological facts. But were we entirely helpless? He thought we could have some principles to go by. One, in his opinion, should be to eliminate from our terminology all names of diseases based on symptoms. They were always misleading. An example was given in locomotor ataxia, for in this particular instance the patient had all the evidences of that disease except ataxic gait. Then there was exophthalmic goitre. He could not recall the number of cases in which he had seen this disease when there was neither exophthalmus nor goitre.

We ought to adopt the term infectious for all diseases dependent upon the entrance of a micro-organism into the body. But he had known the most dreadful cruelty practised upon unfortunate patients with pulmonary tuberculosis from the spread of the idea, first coming from the medical authorities, that tuberculosis was a contagious disease. It ought to be settled in one paragraph as to what constituted the difference between an infectious disease which was communicable, and one which was non-communicable. Another fault which might be corrected was that of having a number of terms for one disease.

But Dr. Thomson would not disturb names whose signification was perfectly distinct and universally received simply because of their mistaken etymology or derivation. The reason was that, like in disturbing anything which had become settled by usage, we would probably introduce more confusion than would be offset by the advantages. But where terms unquestionably led to mistakes in our understanding of disease they should be carefully revised, and he saw no better way than for the Academy to accept the responsibility and appoint a committee which might act with similar committees in other countries as well as in our own. There was one in England which was doing some good work, although it was going slowly, as was characteristic of English conservatism.

Then there should also be some court of adjudication for new terms, so that they might be given some definite signification. This need was especially felt in neurological work. The term neuron, which was only three years of age, being under discussion before the New York Neurological Society, was found already to have six different meanings, or five other than the meaning attributed to it originally by Waldeyer.

Dr. Achilles Rose mentioned as one instance in which he thought it was proper to name a disease after the prominent symptom, the one recently christened "achylia gastrica" by Dr. Einhorn, for in this disease there was deficiency of the juices of the stomach, the cause of which could not always be discovered. Dr. Rose also thought that a great many errors could be avoided in using the Greek for medical terminology, if one would acquire a knowledge of the living Greek. There must be mistakes where one went alone by the dictionary. For instance, a great many disputes had arisen over the spelling of the word "polyclinic." Yet one with a speaking knowledge of Greek could not make the mistake of spelling it with an "i" instead of "y."

Dr. McCourt closed the discussion. He had endeavored to be critical, not hypercritical. He had not attacked any term which he thought it appropriate to retain. He thought long usage was no excuse for perpetuating wrong terms. Many of the terms now in use could not be employed in court without explaining them or doing violence to our conscience. Regarding pronunciation, this was a delicate and difficult feature to deal with, especially in connection with Latin. The Italians came nearest to giving the correct pronunciation of this language. With Greek it was easier, as it was a living language. But our college professors presumed to give the Greeks themselves points in the pronunciation of their own language. They ought to be better informed or more considerate.

Dr. McCourt said he was very glad Dr. Thomson had pointed out the advantage of referring new terms to a committee which should pass upon their propriety and exact meaning before they came to be generally adopted, thus avoiding new errors.

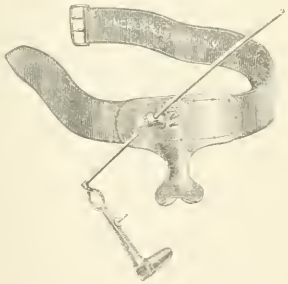
The President stated that the Academy and its sections now adjourned until October; that the library would open only during the day from June 15th to August, and that during August it would be closed for refurbishing.

New Instruments.

A SELF-RETAINING NASAL SPECULUM.

By W. W. DEES, M.D.,
NEW YORK.

The accompanying illustration represents a self-retaining nasal speculum which, in some cases, I have found almost indispensable. The speculum proper is of the ordinary spring variety, controlled by a set-screw. At the back of the spring is brazed or welded



a slotted nib, hinged to a bar which in turn runs to a ball-and-socket joint, fastened to the head-piece of an ordinary forehead mirror. The hinge-joint permits the speculum to be used on either side. The bar can be regulated to any length. The ball-and-socket joint allows any necessary lateral motion. It is fastened to the patient's head by a band, and is easily adjusted to any case. The instrument was made by Messrs. Lincoln & Luchesi, New York.

352 West Twenty-second Street.

Getting Ready for Cholera.—When cholera prevailed in France two summers ago, the health authorities sent word to the mayor of a village in the threatened district to prepare for the disease. After a while he reported that he was ready, and upon inquiry being made as to what precautions had been taken, it was learned that a sufficient number of graves had been dug in the cemetery to bury every man, woman, and child in the village.

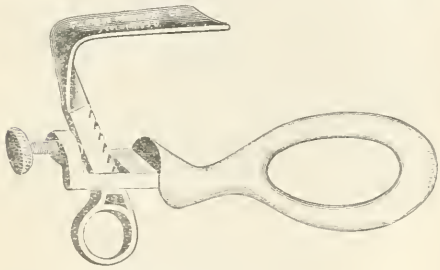
The Bulletin General de Therapeutique, which was for twenty-three years edited by the late Dr. Dujardin-Beaumetz, is now under the editorial management of Dr. G. Bardet. The journal was founded by Dr. Miquel in 1831.

A NEW SELF-RETAINING PERINEAL RETRACTOR.

By D. TOD GILLIAM, M.D.,

COLUMBUS, O.

This retractor is for the dorsal position. It consists of two parts: the retractor proper, and the holder. The retractor has a short blade and a short handle. The handle is notched on its outer aspect, and has a ring at the extremity. The holder has a large ring



at its upper extremity to embrace the hump at the lower end of the sacrum. Below this is a saddle which conforms to the curve of the coccyx. At the lower end of the holder is a device for coupling to the retractor. It consists of a rectangular slot which opens on the left side. Near the upper end of this slot, and running transversely across the same, is a steel pin which fits into the notches on the handle. A thumb-screw at the extremity of the holder, which regulates the inclination of the blade, completes the mechanism. The accompanying cut will give a better idea of the instrument than is possible by a verbal description. It must be understood at the outset that it is not a speculum, as it will not, as a rule, expose the cervix unless the anterior vaginal wall be lifted up, or the cervix pulled down. A retractor should have a short blade, that the parts may be drawn down within easy reach. It should not have broad flanges at the vulvar extremity, as this interferes with the free use of fingers and instruments. The experienced operator will at once see the advantages of this arrangement, while the beginner is apt to be disappointed because he cannot at once see the cervix, or because the vulva, in a measure, closes in and obscures the view. In proportion as a retractor is made with long blades or broad flanges, it is spoiled for operative purposes.

Directions: Have patient on her back with buttocks projecting a little beyond the end of the table, push the holder up under the sacrum until the saddle is arrested by the coccyx; the weight of the body anchors it firmly. Introduce the retractor as you would any other, noting the position of the cervix. With one or two fingers of the left hand on the blade of the retractor, and the thumb under the end of the holder, approximate them by pressure. The index-finger of the right hand in the handle ring now guides it into the slot and applies the teeth to the pin. By increased pressure of thumb and finger, the desired degree of retraction is obtained and held by the notch and pin. The inclination of the blade is changed at will by the thumb-screw. The cervix or other parts are now caught by a bullet forceps and drawn down toward or outside the vulva. The instrument is simple, efficient, and inexpensive, and takes up but little more room than the ordinary bivalve speculum.

A Natural Feet Society.—Some English ladies, residents in China, have started a society to put a stop to the practice of binding the feet of young girls. Chinamen, who resent the impertinence, ask the members of the new society to join them in the formation of a Natural Waist Society, to put an end to tight-lacing.

A UTERINE VOLSELLUM FOR USE IN VAGINAL HYSTERECTOMY.

By HOMER I. OSTROM, M.D.,

NEW YORK.

During the past six months, I have performed forty-three vaginal hysterectomies. Some of these were done for the removal of the diseased uterus, others for uterine fibroids, still others for suppurating tubes and ovaries.

The operation has been greatly facilitated by the use of a volsellum which Messrs. Stohlmann, Pfarre & Co. have made at my suggestion. The cross-bar of the instrument permits any necessary degree of traction, and the broad flat handles, which rest in the palm of the operator's hand, make complete rotation of the uterus possible during its separation from the vagina, broad ligaments, and peritoneum. A further advantage is found in the shape of the teeth, which when fixed, close the os uteri, thus shutting off a frequent source of infection.

42 West Forty-eighth Street.

A TRACHEAL TUBE-GUIDE, OR EMERGENCY TRACHEAL WOUND DILATOR.

By FRANK LEMOYNE HUPP, A.M., M.D.,

ATTENDING SURGEON TO THE CITY HOSPITAL, WHEELING, W. VA.

Anything which might lead to a complication of the simple methods of opening the trachea, or any multiplication of the already too numerous instruments for this emergency procedure, is to be condemned. Yet Dr. Lewis S. Pilcher[1] more than thirteen years ago observed that the surgery of the trachea, in many instances, would be made more certain, more facile, and more productive of good results, if the special conditions which it presents were more carefully studied and met.

One of the most distressing experiences we, as physicians, are called upon to meet, and an experience which comes with almost startling frequency, is that of a child afflicted with laryngeal diphtheria.

During the past year I have had occasion to open the trachea six times for the relief of the stenosis coming with this dreaded disease, and in nearly every instance I have recognized the need of an instrument which could be so quickly and efficiently introduced into the windpipe, that relief would be immediate and that the cannula could be safely and accurately placed.

If the first sign of danger has been appreciated and an early interference has been brought to bear in the case, all will go well and relief will be certain. But, on the other hand, if the tracheotomy has been delayed or the medical attendant has not seen the case until it is in articulo mortis, then whatever is done must be done expeditiously, or life will be extinct.

It is particularly for this latter class of cases that I wish to call the attention of the medical profession to an instrument which may be used where the little sufferer is in immediate danger of suffocation, and where the introduction of a cannula is of supreme importance.

The tube-guide is fashioned like a miniature Sims speculum, as may be seen by the engraving, terminat-

[1] Care of the Trachea after its Incision for the Relief of Croup, MEDICAL RECORD, p. 342 1882.

ing in a probe point, grooved on its convex side like the speculum, but having the two sides converging toward the probe point. When the tracheal rings have been quickly divided and difficulty is encountered in placing the cannula, the probe-pointed guide may be quickly and accurately carried down along the finger and gently forced through the severed rings, and traction made in a direction toward the sternum.

If there be no cannula at hand, and no other cutting instrument but a penknife, with the aid of this instrument a child can be kept alive almost indefinitely until the tube arrives, there being no interference to the ingress of air.

The tube-guide will also facilitate the cleansing process and the removal of membrane, and care in this direction, so urgently insisted upon by Dr. Pilcher,[1] has certainly had much to do with diminishing the percentage mortality after opening the trachea.

The instrument is made by George Tiemann & Co., and is so constructed, and of such a size that it may be carried in the vest-pocket. I have had a three-pronged retractor placed at the other end of the guide for convenience instead of a simple handle.

Let me briefly relate two failures which might have been averted had an instrument of this kind been at hand :

Case I.—W. M——, aged two, laryngeal diphtheria of thirty-six hour's standing—stenosis almost absolute. With the assistance of Dr. R. M. Baird a tracheotomy was performed ; just as the rings were divided the child quit breathing. Retractors and tenacula were used to hold open the severed rings, yet when the cannula was placed, every effort was made to resuscitate the patient, but all to no avail.

Case II.—K. R——, aged four, diphtheritic croup, suffocating dyspnœa. Younger child in same room with tube in neck. Assisted by Dr. James Schwinn, the trachea was speedily opened—an instrumental effort was made to separate the rings and to introduce the cannula ; but the edges of the wound in the trachea were so inverted and the child so far gone, that life was extinct before the cannula was placed.

61 Fourteenth Street.

The Hygiene of the Future.—The great problems in medicine to-day are hygienic, not therapeutic, though therapeutics seems to be getting the better of diphtheria. The most desirable thing in the affairs of man is, first, the making of people healthy, and, second, the making of them happy. The dyspeptic Puritanism which whines over the necessity of suffering as a means of grace can have no place in a superstition-free and scientifically enlightened philosophy. What we want, and what hygiene is yet to give us, are comfortable homes for all mankind, aseptic alike of the germs of zymotic disease and of the taints of the common vices, where noble and healthful men, noble because they are strong and healthful, and sweet and beautiful and healthful women, beautiful and sweet because they are healthful, shall rear their little families of disease-unblighted children, happy because healthful, and giving promise of future attainment in the good, the beautiful, and the true—promises which shall not be broken because hygienic medicine has made the keeping of such promises possible.—Professor H. A. Cottell, University of Louisville.

Correspondence.

OUR LONDON LETTER.

From our Special Correspondent.

DEATH OF PROFESSOR HUXLEY—THE PRINCE AND PRINCESS OF WALES AT HOSPITALS—KNIGHTHOODS FOR THE PROFESSION.

London, July 3, 1895.

Huxley is dead. Many of your readers may have expected this from what I have written as to his illness. As he prefixed an autobiographical sketch to the recent edition of his works, many of the interesting events of his life will also be known to, and recalled by, your readers at this juncture. Though he actually practised the profession for a short time, it is as a scientific worker, and especially as a biologist, that he achieved the great position he held so long, and which makes his death seem to leave so great a blank in the scientific world. His influence with the public was largely due to his great ability as an expositor of science. His literary taste and skill induced many to approach problems they would have shirked under the guidance of many able men. His oratorical gifts, too, were of a high order and very attractive to cultured minds. He has himself stated that his writings cost him hard work, that he thought nothing of writing a sentence three or four times before committing it to the press, and so he cannot be said to have been a born writer or speaker, but like so many more conquered success by industry. Yet his finished and charming style, as well as his labor in producing it, must be considered as proving that he was endowed with excellent literary taste and critical acumen. He would doubtless have succeeded in any walk of life demanding intellect and industry, as those who know how manfully he worked his way to his great position along the rugged road of science will be the first to acknowledge. The profession was proud of him as one of its members, and he wielded great influence in maintaining and promoting scientific culture in our ranks—the more so, perhaps, that the biological sciences claimed so large a share of his attention.

In 1883 he became President of the Royal Society. In 1892 he was made a privy councillor, a distinction conveying the title Right Honorable, which is, I think, unique as a recognition of scientific services, being chiefly earned in political strife. University degrees and Academy fellowships had, of course, been previously showered upon him from all quarters.

Theological problems seem to have had a strange attraction for him and led him into warm controversy. In this he displayed his courage whoever might be his opponent, and did not hesitate, as will be remembered, to close with so redoubtable a master of logomachy as Mr. Gladstone himself. Possessed of tenacity of purpose amounting almost to obstinacy, he had to be driven from any position he had taken up before he would relinquish it, thus illustrating the quality on which the English have been rallied, of not knowing when they are beaten. He originated the term "agnostic," thinking it the antithesis of the Gnostics of the Church, who professed to know so much. Attempting to apply scientific methods to the Bible in all its parts was sure to be unpopular, and some of the controversy he thus kindled was perhaps as useless as it was bitter. Moral or religious problems cannot be solved by mechanics or mathematics. In the new number of the *Westminster Review*, which, by a coincidence, appeared as the professor lay dead in his house at Eastbourne, there is an article by a writer who proclaims himself an agnostic and devoted disciple, which nevertheless consists of a statement of difficulties in understanding the views of the great agnostic. This seems at least to show that Huxley's clear style and direct argument

failed sometimes to make his philosophical opinions comprehensible to some of his ardent admirers.

Huxley's friends were a multitude, and they are vying with each other in extolling his constancy, simplicity, modesty, love of truth, and other virtues; while the medical friends who attended him through his last illness were charmed with his patience, cheerfulness, and consideration for them. He died on Saturday, and yesterday his remains were committed to the grave at the Finchley Cemetery, where two of his children are buried. At Charing Cross Hospital, where he was a student, there is already a movement to raise a memorial to him in a form to benefit the school.

The Prince of Wales and the Crown Prince of Denmark went to St. Bartholomew's Hospital on the occasion of the consecration of a new Masonic lodge, named after Rahere, the founder of the hospital. The Prince of Wales is Grand Master of the English Masons, and the Prince of Denmark of the Danish Masons. The Rahere lodge will be another strong link between doctors and Freemasons.

The Prince of Wales displays a good deal of interest in medical institutions. Quite lately H. R. H. helped the bazaar for St. Mary's Hospital, and next Monday he is to lay the foundation-stone of the new buildings of the Royal Medical Benevolent College, and is to open the new buildings of the Royal Free Hospital on the 22d—on this occasion being accompanied by the Princess. He has accepted the office of Chancellor of the University of Wales.

Three knighthoods have fallen to the profession. Edinburgh has one in the person of her distinguished Medical Officer of Health and Professor of Medical jurisprudence—Dr. (henceforth Sir H. D.) Littlejohn. Dublin has two: very proper, no doubt, from a fallen Home Rule government, but both are worthy recipients, viz., Mr. Thornley Stoker and Dr. Christopher Nixon.

OUR PARIS LETTER.

MEETINGS OF THE ACADEMY OF MEDICINE—HOSPITALS MEDICAL SOCIETY—SURGICAL SOCIETY—BIOLOGICAL SOCIETY.

PARIS, July 6, 1895.

THE last meetings of the four leading medical societies of France are fraught with interest to the general practitioner as well as the specialist. At the Academy of Medicine a discussion on the prophylaxis of diphtheria was introduced by Professor Dieulafoy, who demonstrated that a clinical examination alone was insufficient to make a positive diagnosis between herpetic and diphtheritic angina; such an examination was likewise incapable of giving us information regarding the duration of bacillary virulence. One means only permits us to separate surely and unerringly diphtheritic angina from others. One means only permits us to know whether the bacilli persist in a state of virulence in the mouths of patients. That means is the bacteriological examination.

M. Cadet de Gassicourt requested the Academy to formulate a petition to establish in Paris laboratories directed by trained specialists, and to which physicians could send for examination fragments of false membranes and mucosities taken from individuals suspected of having diphtheria or convalescing from that disease.

M. Rochard pointed out the danger to the public health caused by alcohols called superior, and by the essences with which liqueurs, as dispensed in cafes, are made. The consumption of alcohol has doubled in France during the last few years. At the same time the average of crime has increased with alarming rapidity. It was proposed, in order to counteract this, to limit the number of shops, to demand a good moral character of wine-sellers, to increase the duties on alcohol, and to prosecute vigorously frauds of all kinds. The question of the influence of alcohol in the production of phthisis was next discussed, and it is noteworthy that at Rouen and Havre, where the quantity of alcohol consumed per capita annually is 14 litres, there are 402 and 522 deaths from phthisis in 100,000 inhabitants; while at Toulouse, where the quantity used is 2 litres a head, there are only 290 deaths.

M. Bordaz read a paper on the use of permanganate of lime as an excellent non-caustic antiseptic. It is, however, doubtful if it is better than the permanganate of potash, which possesses also microbicide properties.

At the Société Médicale des Hôpitaux M. Gallard reported a case of acute thyroiditis, terminating in resolution. The patient was a woman of forty, nervous, thin, and physiologically miserable, having tumefaction of the thyroid body consecutive to the grippe. There was great pain in the right cervical region and difficulty of swallowing, accompanied by fever and an enlargement of the base of the neck. On a level with the right lobe of the thyroid body, there was a tumor about the size of a hen's egg, redness, and pain; on the left side the tumefaction was less accentuated. Belladonna ointment was applied to the swelling, with antipyrine and purgatives internally, beginning on March 23d. On the 26th, amelioration, less pain, less difficulty in swallowing; pulse, 96, temperature, 38.5° C. On the 27th, pulse, 100, temperature, 37.5° C.; the right lobe of the thyroid body is reduced to the size of a horse chestnut. On the 29th, *restitutio ad integrum*, no fever, no trace of thyroid swelling. There were, however, several attacks of palpitation and tachycardia subsequently, the heart beating from 128 to 140 per minute.

M. Legendre reported the case of a child suffering from generalized eczema complicated with obstinate gastro-intestinal trouble. The patient was five years of age; the eczema, which at first seemed to yield to good hygienic measures, began after a few weeks to spread rapidly, and soon extended over the entire integument; the child lost flesh and diarrhœa set in. All the antidiarrhœa treatments were tried without success, including hypodermic injections of physiological serum. The child continued to waste steadily. The first nurse, an alcoholic with acne, had been discharged; the second got off with an abscess of the mammary gland; the third with an erythema of the breast. Virulent stomatitis now made its appearance, the temperature rose suddenly to 40° and even 41° C., and the child died without cardiac or pulmonary complications of what M. Legendre calls bucco-intestinal septicæmia.

At the last meeting of the Surgical Society M. Richelot continued the discussion of a new method of vaginoabdominal hysterectomy.

At the last meeting of the Biological Society, Professor Hanot reported a case of acute miliary tuberculosis in a man sixty-one years of age. The tubercle, unique, rounded, firm in consistency, about the size of the head of an ordinary pin, and projecting slightly into the lumen of the vessel, was situated in the superior portion of the pectoral aorta. The cuts showed an absence of blood-vessels, the presence here and there of the bacillus of Koch, and a few giant cells, the centre being in a state of caperification: all of which attest rapid formation; the rest of the aorta was free from lesion, as regards the internal and middle tunicas; on the external tunic was a small inflammatory nodule of no particular pathological importance. It is well known that the tubercular bacillus enters the circulation in two ways, generally: by the lymphatics and by the veins; the entrance by the arteries is probably much more frequent than is known: in fact, Koch, Mugge, and Cornil have each reported cases of tubercular deposit in the vessels of the bronchial ganglia, the internal tunic of the pulmonary artery, and the meningeal arteries, respectively.

M. Langlois had studied with M. Atanazio, the action of the salts of cadmium on cold-blooded animals.

In injecting into a frog seventy centigrammes of the sulphate of cadmium by kilogramme of weight of the animal, they caused a state of stupor in which the excitability of the nerves remained intact. They concluded from their experiments that cadmium acts upon the ganglionary system of the heart.

M. Lapicque affirmed that he had found an iron hydrate mostly of colloid form in the liver of a diabetic patient, and M. D'Arsonval related a number of experiments proving that ozone has no antiseptic power.

A NEW INTRODUCTOR AND EXTRACTOR FOR INTUBATING THE LARYNX.

To the Editor of the Medical Record.

Sir: In describing my "New Introductor and Extractor for Intubating the Larynx," in the issue of June 15th of your journal, I did not at the time consider it necessary to mention that the instrument had been ordered in February. The extractor and tube with wire rim attachment were ready for use in the beginning of March. The publication of the instrument was delayed because the introductor had to be altered many times before reaching its present state of perfection. I hope you will, in justice to me, give these few lines space in your valuable publication.

Yours respectfully,
David C. Lewinthal, M.D.

CRANIOTOMY AND THE LAW.

To the Editor of the Medical Record

Sir: The article on "The Catholic Church and Obstetrical Science," Medical Record, June 22d, is interesting from the fact that it defines in full the attitude of a powerful religious organization on a question of public policy. Professor Sabetti's able article places the four ecclesiastical decisions on the question of the justification of craniotomy in the best possible form from the stand-point of the body he represents. "The admission therein contained, that craniotomy is one of those surgical operations which are and must be called *directe occisivæ*, truly murderous, precludes every other abstract and otherwise possible interpretation of the *tuto doceri non posse*, except the practical one, *i.e.*, that craniotomy is unlawful, morally unlawful always, and intrinsically unlawful. . . . And to speak of 'science' and 'necessity' that we may connive at such a crime is, to say the least, ridiculous. Science is advanced only by truth, and necessity, however great, cannot be admitted as an excuse for crime."

These conclusions of Professor Sabetti are theological. They are significant in this: that good theology may be bad public policy, and also that ecclesiastical deliberations are not always in harmony with Anglo-Saxon law.

The question is a legal one *per se*, against which any conflicting view is untenable. The subdivisions under which the common law takes consideration of craniotomy are answers, in themselves, to the conclusions quoted above, under the unfortunate necessity which demands the operation.

The standing in law of an unborn child is definite. his civil rights are on an equality with those guaranteed him after birth. He inherits; may take under marriage settlement, or specifically under a general devise as a child, and may obtain injunction to stay waste. He is a citizen under common law, his destruction by craniotomy is therefore homicide at common law after quickening. The law provides specific defence for justifiable homicide, a part of which, leading up to the special form we are discussing, is classified as follows:

Repulsion of felonious assault, *vim vi repellere licet*, a cardinal principle of Roman law.

Prevention of felony, in which a *bona-fide* belief that a felony is in process of commission, justifies the homicide of the felon.

The execution of malefactors by an executioner, under the law, in furtherance of public justice.

Superior duty. It has been observed that there are cases in which a surgeon, when called upon to determine whether a critical operation is to be performed, may undertake such operation, though the prospects of success are slight, if the alternative is certain, miserable death in the natural progress of the disease.

The law of necessity. The same law which lies at the basis of jurisprudence in this respect justifies the sacrifice of the life of one person, when actually necessary for the preservation of the life of another, when the two are reduced to such extremities that one or the other must die. This is the *necessitas non habet legum*. It is, however, strictly limited under the law; canon jurists hold that the right can only be exercised in extremity and in subordination to general rules of duty, to which such a necessity as the one under discussion must be subordinate.

The plain reading of the general law is: "It is a defence that the destruction of the child's life was necessary to save that of the mother." The Ohio statute, declaratory of the common law, was enacted in protection of physicians who are confronted with this dire necessity. It provides that craniotomy may be performed when necessary to save the life of the mother; hence, when the question is between an unborn infant's life and that of the mother, the mother's is to be preferred.

This doctrine of the common law is carried intact into other contingencies of life, *i.e.*, as between a sailor and a passenger; supposing there are more than enough sailors for navigation, the passenger must be preferred. Upon the authority of Lord Bacon, it has always been held in law and in fact that, when two shipwrecked persons get on the same plank, and one of them finding it not able to save them thrusts the other from it, whereby he is drowned, it is justifiable homicide.

These citations on justifiable homicide are a part of the criminal law of the United States, except where modified by legislation. To this authority of law for the operation of craniotomy sound principles of public policy, too universal almost to need mention here, would dictate that: a physician, from his general experience in obstetrics, and from his special knowledge in a particular case, aided by the counsel of one or two other reputable physicians to whom he has communicated all he knows about the case, and who, from an examination of the patient and in full possession of all the facts, give a concurrent opinion, that in order to save the life of the mother the life of the child must be sacrificed, the soundest principles of public policy demand that the mother shall be saved. The physician has but one proposition before him: to save one life at the expense of the other. He is morally inadeqate and intrinsically unworthy if he fails to do so, when there is no other recourse. The duty he owes to society at large in saving the mature and useful life of the mother as against the life of the child, which in its useful relations to the social body is yet immature, is above and beyond adverse legislation. He is justified under the plain reading of the law; under the law of necessity, and under the law of superior duty, all of which have their foundation in the overwhelming sentiment in the human family, that the operation is intrinsically and fundamentally right. As to the moral lawfulness of this vexed question, it is one which in the nature of the case cannot be settled by an ecclesiastical body, however great its services to humanity may be or may have been; it is a question beyond its jurisdiction and may be submitted in the following broad application: Two wrongs do not make a right, one comes nearer it.

The letter of the common law and the universal protection man gives to the life of his mother leave the physician no room to escape the operation when the unfortunate necessity confronts him, *i.e.*, when symphyseotomy cannot give the necessary outlet, and the physical condition of the mother prevents Cæsarean section. It is intrinsically lawful by this principle: every condition in life is dependent on the possession and preservation of life. On this point theological law ought not to be at variance with the *sina qua non* in common law.

Xenia, O., July 1, 1895.

BICYCLING FOR WOMEN.

To the Editor of the Medical Record.

Sir: One is loath to offer an objection to anything which attracts women to physical exercise, yet one should not be blind to the dangers attending it. Much has been written upon the subject of bicycling for both sexes; but in the case of women, after the opinions of some old fogies on its propriety have been aired and rejected, the main discussion has been upon the toilet. Garments of the bifurcated plan have been much in evidence, as they concerned the style as well as the comfort of the cycler.

In all the discussions, the physical effects of the wheel have held a minor place. Some have experienced a gain in weight, others have lost, and many victims of obscure "nervous" conditions have reported themselves improved by the moderate use of the wheel.

It is yet too early to judge of the benefits or injuries due to cycling, but positive danger should be clearly indicated and removed. One danger is the saddle, which is physically and morally injurious to women. Everyone is familiar with the general form of the ordinary saddle, and knows how entirely inadequate is the support given to the body, which needs a surface at least wide enough to receive the tuberosities. Otherwise the support is thrown upon the soft parts never intended for that purpose, while the arms and legs transmit a portion of the weight.

The saddle of a bicycle has been compared to a saddle for a horse. A woman in a saddle astride a horse has proper support for her body and offends neither modesty nor common-sense though she shock conventionality. But on a bicycle with the present form of saddle, while conventional, she offends her physical nature. For the saddle presses upon the soft tissues which form the pelvic floor, finding its first bony rest at the pubic arch and the coccyx, compressing the soft parts which cover them. This means that these sensitive tissues are subjected to a pressure the evil results of which cannot yet be estimated. Moreover, the impingement and vibration of the saddle can and do act as a sexual excitant. It would seem better for the medical profession to face this fact than to leave it a food for the evil-minded or a subject of jokes. That it is a fact may be verified by a little observation. To this, however, two difficulties present themselves. One is that the psychical sexuality of women is an unknown quantity even to medical men, because of the disinclination of women to analyze or discuss their sexual feelings. The other difficulty is the indelicacy of interrogating women on such a subject, besides the risk of sometimes inducing a dangerous consciousness. Moreover, it would scarcely be expected that women who keep up the practice would be inclined to make such an admission.

The form of the saddle is probably one reason why women ride more gracefully than men, for the position of a "scorcher" would be decidedly painful, if not impossible, for a woman.

In these days it is at least in order to look for signs of degeneration or sexual perversion, and the bicycle may prove a sign. Yet it is far from the intention of the writer to intimate that the large number of women cyclers are in either condition. The only object of this paper is to point out a danger which a proper saddle would remove from a most healthful form of exercise for women.

Theresa Bannan, M.D.

503 Warren St., Syracuse, N. Y.

BICYCLING FOR HAY FEVER.

To the Editor of the Medical Record.

Sir: For the past sixteen years I have had annually an attack of hay fever, beginning about the 20th to the 27th of May, and lasting until about July 15th. In all this time there has been scarcely any variation in the severity of the attacks, the symptoms being violent paroxysms of sneezing with intense itching of the roof of the mouth, extending well into the throat, and inflammation of the eyes, causing severe pain and itching. Occasionally some cough, but never any asthma. I have tried, during these years, all kinds of treatment with no good results, the only thing giving me any relief being a stay at Fire Island, and then only when the wind blew from the sea. Going into the country, or a walk through Central Park even, would bring on paroxysms of sneezing and all the other symptoms.

In March last I learned to ride the bicycle, and becoming very fond of the sport, began in April riding about ten miles a day, until in May I was able to indulge in long country rides of twenty to forty miles. I noticed that the wheeling was improving my general health, although this has always been good. I was looking forward to my annual attack of hay fever this year with more than usual regret, for I fully expected that I would have to abandon my wheeling during this particular period. I determined, however, to keep it up as long as possible, and I noticed after my attack had begun that I never sneezed while pedalling. I rode through Central Park every day with no bad results, but I was still afraid to attempt rides into the country. One extremely hot Sunday I was feeling particularly miserable, and woke up in the morning sneezing. Much against my judgment, I was induced to accompany some friends on a ride around Staten Island, feeling morally certain when I started that I should have to return as soon as I reached the country. There was no sea-air that day, the wind, what little there was of it, being from the southwest, and the most aggravating to my condition. There were also lots of dust, but through it all I rode without a single sneeze, until we stopped at a roadside inn to rest. Just as soon as I got off my wheel all the symptoms of my hay fever manifested themselves in a most marked manner. I suffered intensely for quite awhile, until I mounted my wheel again, when immediately every symptom disappeared. This same experience was repeated three times during that particular ride. So marked indeed was the difference in my condition when wheeling and not doing so, that I kept on experimenting and observing all during the period that I am troubled with the disease, and every subsequent ride confirmed the results herein noted.

It has been evident to me that wheeling has absolutely controlled all the symptoms of my attack, such as the sneezing and itching in the mouth and eyes. It has done so when exposed to all the exciting causes, such as dust, foliage, heat, and sunlight. It is a fact, too, that just as soon as I was off my wheel all the symptoms returned, and I suffered as I have done in previous years, that is, when exposed to the exciting causes. I should say, moreover, that my condition in

the city was also much improved, and that I did not suffer nearly as much as in former years, for which I thoroughly believe bicycle riding is responsible.

Very truly yours,

AN OLD HAY-FEVER SUFFERER.

NEW YORK, July 17, 1895.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 20, 1895.

	Cases.	Deaths.
Tuberculosis	58	70
Typhoid fever	21	10
Scarlet fever	36	3
Cerebro-spinal meningitis	4	4
Measles	190	17
Diphtheria	194	27

Accidents and Ambulance Organization in Berlin.—In Berlin the ambulance organization has been, till recently, very deficient. If, for instance, a person is run over in the street by a carriage the proceedings are as follows: At first a great many people assemble round the victim to give their opinion of the matter. Then several run to the houses of the surgeons in the neighborhood, who probably are not at home. Finally, a policeman, with the assistance of some of the more intelligent of the crowd, place the injured man in an ordinary four-wheeler, and take him to a hospital. Very often this want of ambulance organization has led to serious results, numerous examples of which I could narrate. For night accidents, it is true, there are the Sanitäts-Wachen dressing-rooms in several quarters of the town, where from 10 P.M. to 6 A.M. a medical man and an assistant are on duty. These are maintained by the contributions of the inhabitants of the quarter, and their medical officers have to attend casualties in the waiting-room or to go into the houses if their help is wanted. Their necessity has been often disputed by the profession, for in the night medical men are usually at home and can be found without difficulty. Besides, very often people go to the Sanitäts-Wachen who have not met with an accident, but have some other complaint for which they hope to be treated free of charge. As in the night all the manufactories are closed, the sufferers from really grave accidents derive no advantage from these waiting-rooms, and the *habitués* are principally rowdies who have been wounded in night rows. Notwithstanding all this, the Sanitäts-Wachen have existed nearly twenty years, and now get an annual subvention from the town council of forty thousand marks. They are rather insufficiently furnished with litters, and have no ambulance carriages; but not even the great general hospitals possess ambulance carriages. The only ambulance carriages that exist belong to private undertakers, who also transport sick people, and are in emergency cases difficult to obtain. During the past year a great improvement has been made in this matter by a private society. This society has established at different points of the town Unfall-Stationen (accident stations). There are four principal stations and eight branch stations. At the principal stations there are newly constructed horse ambulances which are ready to start immediately in case of alarm; the principal stations are connected with accident wards of thirty or forty beds, where the injured can be attended till they recover. The branch stations consist of a dressing-room with the necessary instruments and dressing materials, and a room with one or two beds where the wounded can rest some time. At all the stations surgeons and assistants are on duty day and night. They have telephonic communication, so that in cases of accidents the ambulances and surgeons can easily be called. The new organization has already been found to be of the greatest practical use.—*The Lancet.*

The Study of Heredity.—In his address before the Abernethian Society, Sir James Paget drew attention to the great gaps which exist in our knowledge of the laws of heredity. Some of the broad facts of heredity are familiar enough, and are, indeed, too palpable to be overlooked even by careless observers. That gout, cancer, rheumatism, tuberculosis, and insanity, to take a few examples out of many, are often inherited is a well-recognized and certain fact, but, says Sir James Paget, "it has never been studied carefully what may be the result when one parent has one transmissible disease and another has another; what comes if one parent is a member of a cancerous family and another a member of a tuberculous family. Do these two diseases in any respect disturb one another? Are they mutually exclusive, or do they mingle together? We know that acute tuberculosis and acute cancer never make rapid progress together; they seem in so far as that to be antagonistic. But what comes of it when they are mingled together by inheritance? Of that, I think, we certainly know nothing." This is only a specimen of numerous questions which might be put in connection with the subject of heredity, but are for the present without any certain answer. Is heredity more usually through the male or the female? If a son or daughter strongly resembles the male or female parent, will he or she be likely to develop the diseases occurring in the corresponding stock? Why does disease sometimes "skip a generation" only to reappear with increased virulence? Why does the epilepsy of the parent become insanity in the child, or *vice versa?* How comes it that the female transmits the tendency to hæmophilia, but is herself exempt, while the male who suffers does not usually propagate the disease? We might multiply these queries a hundredfold, but they are sufficient to show how much darkness still envelopes so patent and all-important a fact as the inheritance of disease.

Some of the laws of heredity are approximately known, although often their *raison d'être* is inexplicable—as, for example, the law that disease often skips a whole generation and reappears in the generation that follows. This fact has long been observed and is known as "the law of atavism." It seems to involve the assumption that an individual apparently quite healthy may contain in his organism the seeds of disease—*e.g.*, tuberculosis or cancer—and transmit the tendency to such diseases to his offspring, although he has never presented any symptom of them himself. This may be so, but if such a theory be correct it intensifies our conception of the mystery of pathological processes. If it could be shown in such cases that the "latent" seeds of disease (we are compelled to use figurative language in this connection for want of better) remain latent until certain favoring conditions combine to bring them to maturity, the mystery would be materially lessened, but in many cases we have no evidence that such is really the true explanation. It may, however, be regarded as often a probable hypothesis.

The commingling of different and possibly conflicting pathological strains presents, as Sir James Paget points out, a curious and almost wholly neglected field of inquiry. The whole subject of the influence upon each other of different morbid processes is a very obscure one, and many theories on the subject once confidently advocated have had to yield to the hard logic of facts. It was once thought that valvular disease of the heart was almost a safeguard against pulmonary tuberculosis. It is now known that the conjunction of the two diseases, though uncommon, is not excessively rare. So careful an observer and so acute a reasoner as Walshe lent the weight of his authority to the old

idea that habitual exposure to the poison of malaria was an efficient protection against phthisis. This notion is almost certainly erroneous. It was long regarded as doubtful whether two of the specific fevers could coexist. Most observers have seen cases which have inclined them to an affirmative opinion, but the sources of fallacy are many, and at all events such a conjunction is extremely rare. As to the influence upon the offspring of two conflicting pathological strains, we must be content to confess, as Sir James Paget affirms, that "we certainly know nothing." But the subject is not inscrutable, and only needs careful and minute observation in order that some light may be cast upon it. The relations of hereditary cancer and tuberculosis, or gout and syphilis, might be worked out if sufficient attention were drawn to the matter.

A great deal of work still remains to be done in connection with the heredity of phthisis. It is generally asserted that from thirty to forty per cent. of the cases arising in practice occur in infected families, but it is striking how various are the figures given by different observers. Owing to the great frequency of the disease and the probability of infection, it is evident that many cases of apparent inheritance might be otherwise explained. It would be a great gain to practical medicine if we had decisive evidence as to the influence of heredity upon phthisis on the one hand and the frequency of infection on the other. We are still without any quite satisfactory theory to harmonize the apparently certain facts that pulmonary tuberculosis is due to a specific bacillus and that it is frequently transmitted by inheritance. Some French observers published a few years ago evidence tending to show that the actual bacillus of tubercle was conveyed to the offspring through the ovum, but this view has not been generally accepted. Many believe it to be more probable that the parent transmits simply a constitutional delicacy or some peculiarity of the pulmonary tissue which renders the individual more liable to become the subject of bacillary infection; but it cannot be said that we have any certain information on the subject.

Problems of heredity should appeal more especially to the cultured and philosophic of the large body of general practitioners. Hospital work and consulting practice certainly afford an imperfect field for the elucidation of these interesting and important problems. The hospital or consulting physician seldom sees the beginnings of disease, and he has very rarely the opportunity of observing the disease record of an entire family. The general practitioner has such opportunities, and it would be much to the advantage of our art if those opportunities were thoroughly utilized.—*The Lancet.*

Twin Tubal Pregnancy: Retention of Fœtus for Fifteen Years.—According to the Paris correspondent of *The Lancet*, M. Folet, of Lille, has communicated to the Academy of Medicine details of the above extraordinary case. His patient is a woman now aged forty-nine, who, having previously given birth to four children at full term, became, sixteen years ago, again pregnant. When the pregnancy had reached the ninth or the tenth month symptoms simulating labor occurred, blood and membranes being expelled, and the hemorrhage persisting for six weeks. This strange occurrence led to the belief that no pregnancy had really existed. The abdomen remained, however, voluminous, but for fifteen years nothing further happened to disturb her until a year ago, when repeated attacks of peritonitis determined her admission into the Saint-Sauveur Hospital, Lille, where laparotomy was decided upon. The operation was laborious on account of the presence of numerous adhesions of the fœtal sac to the intestines. The sac was, nevertheless, excised almost entire, the too adherent fundus only being left *in situ* and stitched *en collerette* to the lower part of the abdominal incision. Recovery was complete in six weeks, no accident having occurred to retard it. The sac contained two fœtuses—one which had at its death attained the age of two or three months, and the other which had reached the full term of nine months—a phenomenon which is so extremely rare in tubal gestation that only six or seven examples are recorded. The fœtus exhibited at the Academy by M. Folet was not a lithopædion. Its tissues were supple, non-calcified, but were, nevertheless, as dense as cooked bacon. With the exception of certain alterations undergone, the tissues had retained their structure, recognizable by the naked eye and under the microscope.

NEW BOOKS RECEIVED.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE DOMINANT INFLUENCE IN THE MEDICAL PROGRESS OF THE NINETEENTH CENTURY.

BY JOHN SLADE ELY, M.D.,

PROFESSOR OF PATHOLOGY IN THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY; ASSISTANT IN PATHOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS; PATHOLOGIST TO BELLEVUE HOSPITAL.

To anyone who gives thoughtful consideration to the history of the nineteenth century, it must be evident that in it we have the final triumph of scientific realism over speculative philosophy. Whatever the field to which we direct our attention, we cannot but be impressed with the influence upon its progress of the application to it of scientific principles. The many conveniences of living which this process has introduced have clearly demonstrated the practical usefulness of the study of science, and what, a hundred years ago, was regarded as theoretical, delusive, and of but insignificant benefit to mankind, has come to occupy a position of acknowledged usefnlness among all classes of the community. Science is supplanting literature and metaphysics in the curricula of our universities, and scientific schools are undergoing an almost unprecedented development to meet the demands for education in those departments of knowledge which have been found of such utility.

When we search out the influence which has disclosed the scientific principles from which all these practical deductions have been made, we find it to have been preeminently the application of the inductive method of reasoning to the study of the problems of science. Though employed by Copernicus and a few of his associates in arriving at their magnificent generalizations, the general applicability of the inductive method to all departments of scientific investigation, and its inestimable value, were first appreciated by Bacon, at the beginning of the seventeenth centnry. Under the influence of his teaching physical and astronomical science attained a wonderful development, culminating in the Newtonian principle of universal gravitation. During the greater part of the eighteenth century, however, society was dominated by an idealistic tendency, which pervaded all classes of the community, undervalued the benefit to be derived from the inductive method, and materially impeded the progress of scientific discovery. Fortunately, in the general upheaval incident to the French Revolution, a return took place to the inductive method, and in it we find the controlling influence in the scientific advancement of the nineteenth century.

Since the inductive method has been thus potent in the development of general science, and since, as we shall presently see, the progress of medicine during this century is directly traceable to the application of that method to the study of disease, we may be permitted to pause for a moment to consider its essential characteristics.

Inductive reasoning, as the term implies, is the inference of general laws from a consideration of the phenomena which are governed by those laws, and which are susceptible of observation and study. Thus, in physiology, the discovery of the circulation of the blood was the induction of a great natural law as the result of study of the structure of the heart and blood-vessels, and of many of the phenomena of the circulation which were open to observation and experimental investigation. It will be noted that two distinct processes are essential to the inductive method, the observation of phenomena and the accumulation of facts relative to them, and the reasoning from these accumulated facts up to the general law by which they are governed. Fact accumulation and generalization, then, are the essentials of the inductive method.

When, now, we turn from these more general considerations to an analysis of the progress of medicine dur ing this century, we cannot but be impressed with the fact that this century marks the general adoption of the inductive method in the study of disease, the fundamental consideration in medical science. The necessity of the application to pathology of the method of investigation which had been so prolific of results in the natural sciences was indeed impressed upon the minds of John Hunter, in England, and of Morgagni, in Italy, as early as the middle of the eighteenth century, and both these observers collected a multitude of facts relative to the various phenomena of disease. But so out of touch were they with the idealism of the age in which they lived that neither of them attracted a large following, and it is to the French school of the beginning of this century that we must attribute the chief agency in the introduction of the inductive method into medicine.

The magnitude of the change which has been thereby brought about can only be appreciated after a glance at the state of medicine at the end of the last century. At this time we find medicine dominated by all manner of absurd philosophical notions as to the nature of disease, and as to the methods which should be employed to combat it. The natural result of this was the elaboration of innumerable systems or schools of medicine, each presenting its own metaphysical conception of the phenomena of disease. No clearer evidence of their lack of any broad foundation in fact could be desired than the great diversity of the hypotheses which were made the bases of these systems by their inventors. The fundamental doctrine of one of the most widely diffused of these systems was that health depended upon a proper neutralization of all the acids and alkalies of the body. Let acid or alkali preponderate, disease resulted. Diseases were then classified in two groups, according as they were due to excess of alkali or acid, each group being in turn treated by its appropriate acid or alkali. According to another of these systems, diseases depended upon excess or diminution of the vital energy; they were therefore sthenic or asthenic. For the cure of the one the vitality of the patient must be depressed; for the cure of the other it must be stimulated. Homœopathy, the wildest extravaganza of them all, is the only one of these systems which can in any sense be said to have survived to our day. It is from such a state of chaos that the nineteenth century has elevated medicine to a worthy position beside the exacter sciences.

I have already said that the one great factor in the accomplishment of this change has been the application of the exacter methods of scientific research to the study of the phenomena of disease. Whatever the department of medicine we consider, we find the

same persistent effort of its devotees to observe every minutest detail of the diseases with which they deal, in the hope of gaining some knowledge of the nature of the perverted processes which underlie them. The work of this century has, then, been the study of pathology, for this is the science of disease. And as we look back at it we are impressed with the fact that, with the single exception of the introduction of anæsthesia by ether, every material improvement in medical practice has been distinctly traceable to this study. The investigation and elucidation of the structure and functions of the various tissues and organs of the body in health have, indeed, prepared the way for the proper interpretation of the changes of structure and function incident to disease, and without such study much that has been accomplished by pathology would have been impossible; but it is only indirectly and through the medium of pathology that these departments of biology have influenced medical practice, and we must therefore consider their influence as subordinate to that of the study of disease itself. It is, accordingly, to the development of pathology that we must look if we would correctly estimate the influences which have brought about the medical progress of our time.

It has been said that it is to the French school of the early years of this century that the chief agency in the introduction of the inductive method into medicine is to be attributed. The central figure in this school is easily François Xavier Bichat, who, though dying at the early age of thirty-one, has been pronounced by Buckle "the most profound thinker and the most consummate observer by whom the organization of the animal frame has yet been studied." His devotion was pre-eminently to the study of human anatomy and physiology, his object being so to investigate the organization of man as to rise, if possible, to some knowledge concerning the nature and origin of life. It was soon evident to him that, before any conception of the processes underlying life could be arrived at, it was imperatively necessary that there be an exhaustive acquaintance with the structures of which living beings are composed. Cuvier had, indeed, pointed out the immense aid to classification to be derived from study of the internal organs of animals, but Bichat went much further and insisted upon a study of the tissues composing those organs. It is herein that his greatest service to natural science and to medicine lies. From Biohat's time to our own the study of the tissues of plants and animals has absorbed the attention of all biologists.

The immediate corollary from this great generalization of Bichat, of inestimable importance to medicine, was that no true conception of disease was possible without the most minute study of the changes in the tissues which were a part of the disease. "You may observe diseases of the heart, lungs, abdominal viscera, etc.," he says, "night and morning by the sick-bed for twenty years, yet the whole furnishes merely a jumble of phenomena, which unite into nothing complete. But if you open only a few bodies you will see the obscurity speedily give way, a result never accomplished by simple observation if we do not know the seat of the disease." He furthermore established the fact of the tendency of similar tissues to similar forms of disease. "As every tissue has everywhere a similar disposition, since, wherever it may be, it possesses the same structure, the same properties, etc., so it is clear that its diseases must be everywhere the same. Whether the serous tissue belongs to the brain as the arachnoid, to the lungs as the pleura, to the heart as the pericardium, to the abdominal viscera as the peritoneum, it takes on inflammation everywhere in the same way; everywhere dropsies occur in the same way," etc. Bichat was thus the creator of general pathological anatomy, and the untiring nature of his researches may be inferred from the fact that in a single winter he examined more than six hundred bodies. He was also the first to claim for medicine the distinction of an exact science. "Medicine," he says, "will have the right to be associated with the exact sciences, at least as regards the diagnosis of diseases, as soon as we shall everywhere have united with the most thorough and rigorous observation the investigation of those changes which our organs suffer." Thus Bichat, at the very threshold of our century, insisted upon the application of the methods of the natural sciences to the study of disease. If medicine has to-day any just claim to a recognized position among the sciences, it is because of its development along the lines thus indicated.

While Bichat was thus pointing the way for the acquisition of a true conception of the nature of disease, the first of the means of physical examination which so materially aided in the clinical study of disease was being investigated by Corvisart. In 1761, Auenbrugger, a Viennese physician, had published in a small volume a description of a "new invention" for detecting the hidden diseases of the chest by means of percussion. Though based upon most careful and accurate observations of the sounds emitted from the chest when gently tapped with the fingers, both in health and under various conditions of disease, and though received with favor by Stoll and a few others of his associates, the method passed into disuse and the little book was forgotten until unearthed by Corvisart, about 1790. During the following twenty years Corvisart carefully tested the accuracy of Auenbrugger's observations, verifying them by post-mortem examinations as Auenbrugger had also done. In 1808, convinced of the value of percussion as a diagnostic sign, Corvisart made public a French translation of Auenbrugger's book, adding in the form of notes many observations of his own. Percussion almost immediately became a recognized aid in diagnosis among the French physicians of the time, being alluded to by Bayle as early as 1810, in his celebrated work on pulmonary consumption. It was but a step further to auscultation, which by 1819 had been elaborately tested by Laënnec whose great work placed it thenceforth among the indispensable aids to diagnosis.

Thus grew up in Paris the great French school of pathological anatomy and physical diagnosis, which was the guiding star of medicine for nearly half a century. In the development of physical diagnosis the necessity of verifying by post-mortem examinations the conclusions arrived at from the study of physical signs infused a practical interest in pathological anatomy which had been unknown so long as the solution of merely theoretical problems was all that was looked for from its study.

And, similarly, the proof of the accuracy of the information to be gained from physical signs, which was imparted by pathological anatomy, served greatly to increase confidence in the new methods of clinical examination, and to encourage other efforts to adapt physical and chemical principles to the needs of diagnosis. In this way medicine advanced during the first half of the century, the chief aim of its devotees being to obtain, by careful observation of the changes in structure and perversions of function incident to disease, some conception of its nature which should be of practical value in its detection and cure.

When, now, we turn to the past forty years and analyze the influences which have shaped the progress of pathology during that time, we are at once impressed with the pre-eminence of two great generalizations—the "cellular pathology" of Virchow and the conception of the causal relationship of micro-organisms to the infectious diseases.

The underlying principle of the cellular pathology, "*omnis cellula e cellula*," was a scientific induction of the most brilliant nature, based upon a critical study of the cell in its relations to the various tissues. So clear was the demonstration, and so masterly the manner of its presentation, as to have found for it an almost

immediate acceptance, and from the delivery of Virchow's lectures elucidating it, in 1858, until the present time, the cell has been regarded as the ultimate living factor in the production of the tissues of all living beings. The attention of those engaged in the investigation of the changes in the tissues resulting from disease was consequently at once concentrated upon the cell, and new light was thrown upon many obscure subjects in pathological anatomy, notably upon tumors and upon inflammation.

It will be noted that the cellular pathology is in reality but an extension of the principle enunciated by Bichat. The study of the tissues is still paramount, but in the production and development of the tissues the cell is the controlling influence. Nevertheless, to the stimulus imparted to histological study by Virchow we must attribute, in a very large degree, that painstaking investigation of minute structural details which has characterized the study of pathological anatomy in Germany during the past forty years, and which, combined with the careful clinical observation inaugurated there by Krukenberg and Schönlein, has placed that country in the front rank of the nations as regards the medicine of to-day.

When, finally, we consider the last great generalization of the nineteenth century, the conception of the causal relationship of micro-organisms to the infectious diseases, we are impressed with the fact that here, too, we have to do with the induction of a great scientific principle from a mass of more or less isolated facts. Though suggested as long ago as 1762, the idea of a *contagium vivum* of disease has met with general acceptance only after long and careful study. It is unnecessary for my purpose to review the gradual development of the proof which is now so convincing, nor can we stop to consider the many ingenious devices which have been invented from time to time during the progress of the science of bacteriology, and which have made possible the critical study of the minute organisms with which it is concerned. The points which I would particularly emphasize in this connection are, that the conception of the bacterial origin of the infectious diseases is the outcome of the same careful scientific investigation which led up to the generalizations of Bichat and Virchow, and that while these latter, though profoundly influential in developing diagnosis to a high degree of accuracy, had but an indirect influence upon therapeutics, the new conception of infectious disease makes possible its prevention and bids fair to revolutionize its treatment. Already we are in possession of many valuable facts as to the mode of entrance of infectious germs into the body; as to the manner in which they are cast off by those afflicted with infectious diseases; as to their existence during the interval of their escape from one individual and their entrance into another; as to their vulnerability to light, heat, chemical agents, drying, etc.—all of which demonstrate the feasibility of simple prophylactic measures whose general adoption could not but be followed by a very material decrease in the prevalence of these diseases. And, at the same time, the study of the poisons elaborated by the bacteria, of their influence in the production of the symptoms of infectious diseases, and of their relation to the induction of an artificial immunity from them, seems destined to profoundly modify the manner of our treatment of those diseases. This last is still in the developmental stage, but it would seem not improbable that the next decade may witness an evolution in medicine in this respect of the very greatest practical importance.

If, in this brief review of the influences which have directed the course of medical progress during this century, I have omitted to mention a host of material advances which are everywhere apparent in all departments of medicine, it is because I believe them all to have had but a subordinate and insignificant influence in moulding medical thought in comparison to those great generalizations to which I have referred. From one or other of these every advance in every department of medicine has been deduced or has received its final shape. It is interesting to note that in this development all the fundamental problems with which pathology deals have made marked progress toward solution. Our knowledge of the structural changes induced by disease has received much light from the study of pathological anatomy and histology; our knowledge of perversions of function, or symptoms, of disease has been greatly increased by the study of pathological anatomy, physical diagnosis, and bacteriology; and our conception of the causation of disease has been completely revolutionized by the discovery of the etiological relationship of micro-organisms to the infectious diseases. These, then, have been the immediate agencies in the accomplishment of the noble progress of medicine during our time. Upon them all others are more or less dependent. But it should be clearly held in mind that these great principles are all in turn the outcome of the application to medical study of the critical methods of observation and thought which are so essentially a part of the inductive method.

I am particularly desirous that this crystallization of medicine about pathology should be justly appreciated during this century, for the reason that until recently there has been a tendency, particularly in this country, to undervalue the labors of the pathologist as of little importance to practical medicine and of distinctly less usefulness to humanity than the more direct services of the practitioner; and this feeling has operated to deter many, whose training and circumstances eminently fitted them to do so, from undertaking a life-work which appeared to be almost wholly theoretical in scope. The fallacy of this position must be evident. A very important branch of pathology, as has been said, is devoted to the study of the perversions of function incident to disease, and this is of necessity the work of the practising physician, for from no one else can this department of pathology receive advancement. But the pathological anatomist and bacteriologist in their laboratories, in contributing to the progress of pathology have at the same time assisted in shaping the course of medical practice, and have thus indirectly, but yet powerfully, contributed to the amelioration of human suffering. It is not too much to say that, without the facts regarding the nature of disease which the study of pathology during this century has contributed, the medicine of to-day would be but slightly removed from the idealism which prevailed at the end of the eighteenth century. But in another and even more immediately practical way pathology is coming to be of assistance to practical medicine. In the development of every science the solution of many purely theoretical problems must precede the practical application of the principles involved. Thus every science becomes divided, sooner or later, into two departments: the pure science, occupied with the solution of all the theoretical problems of the science, and the applied science, engaged in the application of the principles developed in the study of the pure science to the needs of civilization.

The career of pathology as an applied science can hardly be said to have more than begun. As a part of the general under-estimation of pathology in this country, but little provision has been made for it by our hospitals, the ground, *par excellence*, for its development as an applied science. Until our hospitals shall duly appreciate the value of pathological examinations in the diagnosis, prognosis, and treatment of disease, and shall supply means for the development of pathology as an applied science in a measure commensurate with those which have made possible its splendid progress in its more theoretical department, practical medicine must forego a very large part of the aid which pathology so freely offers. The responsibility of the physician to make use of every means known to medi-

cal science and art in the treatment of his patient has always been keenly appreciated. His failure to do so is even regarded as an offence. But the similar responsibility of the hospital would appear to have been often overlooked in the matter of affording its patients the advantage of such examinations as the pathologist alone can make. What was said by Professor Osler of our medical schools, about three years ago, applies with force to our hospitals to-day: "Thoroughly equipped laboratories in charge of men thoroughly equipped as teachers and investigators is the most pressing want to-day in the medical schools of this country." That this great need of adequate provision for pathology in our hospitals, so long and urgently felt by their medical boards, is beginning to be appreciated by their trustees, is evident from the careful consideration which has been bestowed upon the construction and organization of the pathological departments of a number of our newer institutions of that sort, and from the liberality which has been displayed in a few instances in the endowment of such laboratories. It is greatly to be hoped that the next few years may witness a much further development in this particular direction.

In a science so rapidly advancing as is medicine to-day, it is impossible to predict with certainty what even a year may bring forth, but that it will continue to advance so long as it is dominated by the methods of observation and thought which have induced its splendid progress during this century, there can be no doubt. In the past, a period of epoch-making generalization has often been succeeded by a time of assimilation, during which the progress of civilization has been greatly aided by many practical applications of the laws induced to the needs of the community as a whole. It may be that we shall witness in the medicine of the near future a period of similar application of the great principles disclosed during the nineteenth century. There is certainly very much to be accomplished in this direction, and there is need in its accomplishment for careful scientific work on the part of every devotee of medicine, whatever the field of his activity.

It is to be feared that the responsibility of the physician to his science is too often forgotten; his ability to aid in its progress too modestly under-estimated. It is true that it is given to but few to make the great generalizations of a science. Theirs are the names which win the greatest fame. But the labors of the many who amass the facts from which generalization takes place and without which it is impossible, and who apply the principles induced to the needs of humanity and of civilization, are also worthy of the very highest gratitude of mankind. I would therefore urge upon everyone whose life is devoted to medicine his responsibility to contribute to the advancement of his science, and I would suggest that the methods of careful scientific research which have yielded so much in the past are those which give the greatest promise for the future. Every fact, however apparently insignificant, which is added to medical knowledge is of material assistance in the advancement of the noblest science which has yet engaged the mind of man.

Concerning Spelling Deformation.—It is very gratifying to note that reformers in orthography have not yet undermined the history of language and stamped their obtrusive methods of spelling on every printed page. The simplification of construction and spelling of a language may be an inducement for foreigners to learn that language and give it a better chance to become the international means of communication, but anyone who has studied the life and growth of language and has a love for philology (is it filolojy ?) may give thanks daily that phonetic spelling and the dropping of silent letters has not yet been sanctioned by the best writers.—*Maryland Medical Journal.*

NOTES ON THE NATURE AND TREATMENT OF CHOREA, BASED ON SEVENTY-FIVE CASES IN PRIVATE PRACTICE.[1]

By A. D. ROCKWELL, A.M., M.D.,

NEW YORK.

If any apology is necessary for presenting for your consideration a subject so hackneyed as chorea, the nature of which so many able and careful observers have attempted to solve, and about which discussion and theory have been worn threadbare, it is: First, that any disease, the source of so much anxiety and distress as chorea, cannot be discussed too frequently; second, that my experience has been somewhat large, and gleaned entirely in private and not in hospital practice, upon which nearly all considerations in regard to this subject are based; and third, if I cannot offer anything new in regard to medicinal or hygienic methods of treatment, I am in a position to speak with some authority and confidence upon the methods and results of electrical treatment, a subject even yet, in its relation to this disease, too little understood by the profession in general, and almost altogether ignored by both teachers and writers on nervous diseases. I have long desired to give the impressions of many years' experience in observing the course of chorea and treating its symptoms, and the invitation that I present before the Neurological Section something pertaining both to neurology and electro-therapeutics affords me the opportunity that I have often thought to take.

Chorea has by common consent been put in that class of diseases which presents no constant detectable change in any of the structures of the body, and is therefore termed functional in character. It is, however, more than doubtful whether a functional disturbance, however slight and evanescent, can exist without corresponding disturbance in the nutrition of the nerve elements. Microscopical changes have, it is true, been occasionally found, but not with sufficient frequency to enable us to rely on morbid anatomy to account for the disease, and the nutritive changes that in all probability do take place are too subtle for detection and may, perhaps, ever remain conjectural. Age and sex in their relation to chorea tell us far more of its nature than all methods of post-mortem examination.

The fact that it is almost entirely confined to early childhood and youth, and occurs with far greater frequency in girls than in boys, in the emotional period of life and mostly in the emotional sex, renders it probable that the disease is, in the vast majority of instances, purely functional, dependent upon disturbances or shock to the motor centres of the brain. To illustrate: I once had under my professional care a young girl suffering from what appeared to be a slight neuritis of the radial nerve. On one occasion she was suddenly asked a question in regard to certain facts which she desired to conceal. In her efforts to disguise any appearance of surprise, her facial muscles immediately passed beyond her mental control, and for a few moments the localized movements exactly simulated the familiar examples of facial chorea. It was an excellent example of temporary chorea, having its source in a temporary disturbance in the cerebral convolutions.

Neurasthenia is a functional disease, and it may be either acute and temporary, or chronic and permanent. Just as the fatigue and irritability of mind and body that accompany profound and concentrated mental and physical effort are dissipated by rest and sleep, so the familiar examples of lost muscular control following sudden emotional influences disappear on the subsidence of the cause. In both cases we have to do with facts of cellular nutrition; in the one case with temporary exhaustion, in the other with temporary irri-

[1] Read before the Neurological Section of the American Medical Association, May 8, 1894.

tation. Intensify and prolong the processes of cell exhaustion and cell irritability, and we get in the one case true neurasthenia and in the other true chorea. Another reason for rejecting structural change as the causative factor of chorea lies in the fact that, so far as we have knowledge, there exists no structural change of the nervous and muscular system that will in itself produce chorea. Embolism, to which it has been ascribed, produces, so far as we know, symptoms of a far different character. It is associated with head pain, vertigo, and nausea—at least at its outset—hemiplegia of varying degrees of severity, and, when right-sided, with aphasia together with other disturbances of speech. Then it must be remembered how serious are its sequelæ, how apt it is to recur, and to what extent nutrition is impaired. The occasional presence of embolic particles found in fatal cases of chorea hardly offers sufficient basis for such a theory. But that chorea must be regarded as a disease of the central nervous system, either primary, or secondary to peripheral irritation, can hardly be questioned. As all movement as well as all thought has its origin in the brain, it is inconceivable that disordered muscular movement such as characterizes chorea can depend upon peripheral influences alone. In deference to our inability to point out objective pathological changes, we sometimes speak of the psychical origin of chorea, yet in the last analysis we fall back on disturbance of the motor cortex.

In a large proportion of choreic cases, especially among the poor, anæmia exists, and in another large proportion of cases fright is the exciting cause. Some time ago a child was brought to me, suffering from "nervousness" and extreme anæmia. I prescribed what seemed to be necessary and for a time saw no more of her. While engaged on this article, the mother again returned with the child, suffering now from an acute and violent attack of chorea, the exciting cause of which was fright. These two elements of causation, fright acting upon a nervous system weakened and irritable through its vitiated blood-supply, seem to me to give great strength to the theory of malnutrition of the cortical ganglion cells, as the seat and efficient cause of chorea. The analogy existing between certain nervous diseases that are attended by no definite and positive vaso-motor changes is interesting and suggestive. Influences, the same in kind that result in diabetes when acting on the nervous system of a man, result in hysteria when acting on the emotional nature of a woman, or in chorea when it is the tender and susceptible nature of a child.

Conflicting as are the opinions relating to the pathology and the treatment of chorea, there are certain facts in regard to the disease upon which all experience agrees. Like Basedow's disease, whose pathology is as doubtful as that of chorea, it occurs far more frequently in the female than in the male. In my own experience its exciting cause, in the majority of cases, can be traced directly to fright or other emotional causes, and in this it again bears some resemblance to Basedow's disease.

With increasing years the disease rapidly decreases in frequency, but becomes far more intractable, and even dangerous to life.

Notwithstanding my belief, based upon these seventy-five closely observed cases, that the majority are in their essential nature central—although neither organic nor structural in the ordinary acceptation of these terms—yet a few have seemed to me to depend upon reflex influences, both as exciting and continuing causes. Peripheral sensory irritants, such as a redundant prepuce with collection of smegma, intestinal worms, and ocular defects, have all within my own experience been the undoubted cause of chorea. In the case of a redundant prepuce, an operation performed by Dr. Charles McBurney, at my request, resulted in the prompt recovery of a case where the symptoms had been persistent for several months. In a second case, where I finally suspected worms to be the cause of persistent choreic symptoms in a boy aged eight, a dose of santonine resulted in the expulsion of no less than ten of the common round worms and all of considerable size. This patient also promptly recovered. In a third—a case of ocular defect—an operation by Dr. George Stevens resulted in too prompt an alleviation of the symptoms to allow of any doubt as to its direct efficacy. But reflex influences are altogether exceptional, according to my experience, in the production of chorea.

Where the causes above enumerated exist once in connection with choreic symptoms, they occur a thousand times without any such connection. It is the pseudo-choreas, the various habit spasms, that seem to be most benefited by correcting the anomalies of the ocular muscles and errors of refraction, and not the ordinary true chorea of childhood.

Notwithstanding all the investigations of and the statistics offered by those who have written upon this subject, I have been unable to satisfy myself that between rheumatism or endocarditis and chorea there exists any constantly direct relation as cause and effect. The frequency with which a soft systolic murmur is found associated with chorea must be admitted, and also the results of post-mortems showing endocarditis and the presence of vegetations on the cardiac valves; but these relations have been analyzed with sufficient thoroughness to leave little doubt but that they are mostly accidental, even if in certain statistical tables they are found with suggestive frequency. In epilepsy, in anæmia, in the muscular relaxation associated with certain neurasthenic cases, we not infrequently detect a cardiac murmur, the same apparently as the ordinary choreic murmur. While these murmurs may be, and probably are due, in many if not most cases, to mitral regurgitation, yet they speedily disappear with no permanent structural harm. The temporary defective action of the mitral valve is believed to be due to altered nutrition or innervation. Certainly the functional derangement of the action of the valvular apparatus is sufficiently evidenced by the readiness with which the murmur disappears as the disease improves.

If rheumatism is the efficient cause of chorea through the action of its sequel, endocarditis, then it is hardly necessary to say that the endocarditis should precede the chorea. On the contrary, it precedes it only in a very small proportion of cases when they are associated, and in a large number of cases no evidence of endocarditis can be found. As a reflex cause endocarditis may occasionally be responsible for chorea, as are defects of the eye, or intestinal worms, or redundant prepuce; but like these irritants, it may and does exist a thousand times without any relation to it whatever. Most of the cases that have come under my observation have been carefully examined for evidences of heart disease, and in more than one-half of them there could be found no murmur of any kind, and in only a very small proportion was there any history of aches or pains that could possibly be attributed to rheumatism.

One of the strongest arguments against the rheumatic origin of chorea is the fact that, as related to boys, girls suffer from chorea in the ratio of three to one, while rheumatism affects boys far more frequently than girls. Of the fifteen among my own cases of chorea that gave a history of rheumatism, ten were boys and only five girls. These observations are very much in accord with those of Meyer,[1] who, out of 121 cases, found that only nine per cent. had rheumatism, thirteen per cent. heart symptoms, and two per cent. the two combined; and with those of Leroux,[2] who, out of 80 cases of chorea, found only 5 clear cases of rheumatism and 14 with heart complications. Of these last, 5 were mitral lesions, and 9 simple anæmic and extracardiac souffles.

Much stress is often laid upon the degree of disturb-

[1] Berliner klinische Wochenschrift, July 4, 1890.
[2] Revue Mensuelle des Maladies de l'Enfance, Paris, June, 1890

ance of the mental function in chorea. My observation of the disease, as it occurs in children who are well cared for both as to mind and body, is that there is seldom any mental defect. Sometimes a young child will seem dull without really being so, and the parents and friends of the unfortunate little patient will act along this false hypothesis, to the child's detriment. In chorea the muscular movements are not in harmony with the will. The child, knowing herself unable to give correct expression to thought and desire, manifests, in the presence of strangers especially, a distrust and timidity not in accord with an acute mental state, while the operation and condition of the mind, as registered in the facial expression, are observed and misinterpreted because of the constant facial deformity. The imperfect muscular co-ordination occasionally extends to the vocal apparatus, rendering the speech somewhat indistinct and jerky. In other cases the patient talks very well when once started. At first the lips may be seen to move, but it is several seconds before there is any articulate sound. One of the brightest children I ever knew had this symptom, and for a time was credited with being below the normal level mentally. There is a class of choreic cases very commonly met with where the inco-ordination of movement is ordinarily slight, but when conscious of observation the muscular disturbance becomes exaggerated. There is another class where a contrary condition exists. The movements are greatest when the patient is at play and unconscious of observation, but by an effort of will the child can control these movements.

It is among patients of the first class that mental defects are most often thought to exist; these cases are, however, far less apt to be dull than those of the second class, and recover with greater rapidity. I do not find that ordinary chorea is distinctly or directly hereditary, but, among the better class at least, it will be found that in an unusually large number of cases the child inherits a neurotic tendency.

This neuropathic heredity is said to be in the proportion of about one-sixth, but in my own experience it is very much greater. The theory advanced by Garrod that the rheumatic poison occasions a temporary overgrowth of connective tissue in the nerve-centres, resulting in chorea, has little to recommend it; but the infectious theory, about which so much has lately been said, has points of strength both from an anatomical and a bacteriological stand-point, since there is found in the nervous system a special bacillus pathogenic for microbes. Bacteriological and experimental researches have been made by Pianese[1] in fifteen acute cases of chorea. In three of these cases a bacillus was isolated from the blood, and inoculation caused the appearance of the disease in dogs. In the opinion of this author, the theory of the infectious origin of chorea is far more satisfactory and complete than all other theories. Triboulet[2] has reported three cases of secondary infection by the staphylococcus in chorea, and gives it as his opinion that in four-fifths of the cases infection could be traced as the causative factor of the nervous trouble.[3]

But, however suggestive the various theories and investigations as to the nature of chorea, nothing is more certain than that no constant pathological change is associated with it, and we must fall back upon the theory of its neurotic functional origin. Its almost invariable benign nature and tendency to recover is the strongest evidence that it can depend upon no serious or persistent pathological change.

As regards the therapeutics of chorea, there is much to be said, both from the stand-point of those who believe in the necessity and efficacy of therapeutic measures, and from that of others who look upon it as practically a self-limited disease, which recovers as readily without as with treatment. Self-limited it is not in the sense that we speak of the self-limitation of scarlet fever or measles.

We cannot abort or very much, if at all, cut short the course of these diseases, but that measures can be adopted for the relief of associated symptoms, or the arrest of complications, is admitted. We can, however, not only very markedly alleviate the severity of choreic disturbances in aggravated cases, but can do what cannot be done in the so-called self-limited diseases, shorten the duration of the disease. In regard to certain hygienic and sanitary methods of dealing with chorea, there is very little diversity of opinion. It is agreed that rest is a most important factor in most cases, and in those more serious the rest should be complete and continuous.

In the less severe cases, moderate exercise in the open air is allowable and beneficial, but in no case should a child with chorea be allowed to engage in rough-and-tumble sports. Sleep, and much of it, is essential, and when it is greatly disturbed we are justified in aiding it by hypnotic measures. The food should be nourishing, but simple. If the appetite be poor, it is allowable, and even desirable, to tempt it by daintily prepared food of judicious selection, but to attempt to stimulate appetite by artificial means is even more unjustifiable in the case of a child than in that of an adult. Far more harm than good is done by forcing food when nature cries out against it.

To enumerate all the remedies that have from time to time been advocated almost as specifics in the treatment of this disease would only serve to indicate the limited data of experience upon which opinions are based.

Few of them have stood the test of time and trial, and the general opinion is that medicinal treatment is extremely unsatisfactory. By this I do not mean to say that, in individual cases, we may not be reasonably sure of the efficacy of certain remedies in alleviating symptoms and shortening the duration of the disease. There are indeed well-authenticated cases of long duration that have persistently resisted various accredited methods of treatment, and finally recovered promptly upon the adoption of some other old or some new and untried remedy.

A notable illustration of this is related in Reynolds's "System of Medicine," where a distressing choreic affection of the muscles of the neck had existed for nine years, defying all measures for its relief. Hypodermic injections of arsenic were attempted with almost immediate relief and final recovery. But I would say that there is no consensus of opinion as to which of the many drugs used is the most effective.

Arsenic has undoubtedly the preference, but proves too often absolutely inert. There can be no question, for example, of the authenticity of the case just alluded to, and encouraged by the success in that instance, I thought to duplicate it in an obstinate case somewhat similar in character, by the same method of treatment, but without the slightest result. Now, although I have from time to time tested nearly all the well-recognized remedies in the treatment of chorea, yet there is but one remedy that I have used with more or less persistency in almost every case, and that is electricity. I am not so credulous as to suppose it to be curative, or even markedly beneficial, in every case. Occasionally, on the contrary, it has seemed to be positively contra-indicated, although long experience inclines me to believe that this seeming susceptibility to the current is due more to a failure to correctly differentiate in the selection of the kind of electricity and injudicious methods of application than to any adverse idiosyncrasy present.

In the light of my own personal experience in the treatment of chorea, the opinion expressed, more than a quarter of a century ago, by a distinguished physician is of much interest. "Electricity," he says, "is another

[1] Riforma Medica, Naples, July 20, 1894.
[2] Revue Mensuelle des Maladies de l'Enfance, Paris, December, 1891.
[3] Thèse de la Faculté de Paris.

agent which requires a passing mention in this place, though all that can be said respecting it is, that as yet there appears to be little or no reason for placing any confidence in it as a means of treatment. Whether this will always be the case—whether there are not modes of using electricity which will have the effect of quieting choreic and analogous movements, remains to be seen. I suspect that there are such modes, and that they will be beneficial, but I have not yet the facts to justify the expression of a belief on the subject."[1] Electricity benefits chorea on the same principle that it benefits neurasthenia or hysteria and many other functional nervous diseases, because of that indirect improvement in nervous force which is a part and a result of the general improvement in nutrition. While electricity is neither life nor nerve-force, it aids in sustaining both life and nerve-force, as do light and heat; not by direct transformation, but indirectly through its influence over nutrition.

This influence over nutrition, together with musculosedative effects, are brought about in greater or less degree by various methods of electrization, by general faradization, especially with the high-tension coil, central galvanization, static electrification, and even by peripheral galvanization. To obtain temporary musculo-sedative effects, there is no method that equals the depolarizing method of central and peripheral galvanization, by which is meant the elimination of either one or the other pole. In this way the neutral point is thrown outside the body, and the part or parts brought under the influence of either the negative or positive pole alone, as desired. Static electricity (positive) is also sometimes useful in chorea in calming nervous excitement, and as an aid to nutrition.

But the two methods that I have found, on the whole, to be the most effective in the treatment of chorea, are central galvanization and general faradization. These two methods properly differentiated and used, either alone or in alternation according to the indications in each individual case, are capable of doing much not only in alleviating the violence of the choreic movements, but in shortening the duration of the disease.

A somewhat useful point in the way of differential indication for the use of the two currents and the two methods of application, which has been forced upon me by repeated observation, is the following: For children of full habit and in that excellent condition of general health which we not infrequently see among the victims of chorea, the galvanic current is to be preferred. For those, on the contrary, who are weak and anæmic, with impaired nutrition, the faradic current is far more grateful, and is followed by better results both immediate and permanent.

TWO CASES OF TREPHINING FOR TRAUMATIC EPILEPSY, WITH REMARKS.

By LEONARD FREEMAN, B.S., M.D.,

DENVER, COL.

RECENTLY SURGEON TO CHRIST'S HOSPITAL, PROFESSOR OF SURGERY WOMAN'S MEDICAL COLLEGE, PATHOLOGIST TO CITY HOSPITAL, ETC., CINCINNATI, O.

CASE I.—The first case was that of a well-developed white man, twenty-seven years of age, who entered the surgical service at the Cincinnati Hospital, of which I had charge at the time, on August 3, 1893. About ten years previous he received a load of duck-shot full in the face, at short range. The sight of both eyes was destroyed, and a number of shot lodged about the face and head, where they could be felt beneath the skin. The skull was perforated in the centre of the forehead. Some necrosed bone was subsequently removed from this point, leaving a depressed and puckered cicatrix the size of the end of a finger.

Nine days after the injury, according to the patient, paralysis of the entire left side of the body suddenly set in, while he was standing and voiding his urine. Seven days after the injury an attack of epilepsy occurred. At first the convulsions took place but once a month, but gradually became more numerous, until, when he entered the hospital, he sometimes had as many as five a day.

The convulsions were general, beginning, according to the nurse and the interne, in the right arm. The patient became unconscious, frothed at the mouth, and at times bit his tongue, the right elbow and knee becoming firmly flexed. Cyanosis and stertorous breathing supervened, followed by considerable *malaise* and nausea.

The patient's intellect was cloudy and heavy, so that he expressed himself laboriously. He was at times somewhat delirious. Much pain was often experienced over the back and top of the head. The left side of the body was paretic, the hand and arm being almost useless, although the left leg could be used sufficiently well to enable the patient to shuffle about the ward. According to himself and his friends, most of the above symptoms had been steadily increasing.

Dr. F. Kebler and Dr. Joseph Eichberg were called in consultation, and an operation decided upon. Owing to the fact that the convulsions, as observed, seemed to begin on the right side, although paresis was confined to the left, it was deemed better to trephine the left side of the skull first, and then, if necessary, make a second opening on the right.

The operation was made on August 21, 1893, chloroform being used as an anæsthetic. The centre of the fissure of Rolando was indicated by marking the bone with a drill, and a large horseshoe flap turned down. The skull was found to be so enormously thick that it could not be penetrated with the inch-and-a-half trephine at first employed, and a smaller and deeper instrument had to be substituted. After separating the dura, which was firmly adherent, the opening was enlarged with the rongeur forceps. On making a semicircular incision in the dura, the brain, which was normal in appearance, bulged strongly forward. A grooved director was inserted about one and one-half inch into the cerebral tissue in all directions without detecting anything abnormal. The dura was then sutured, the button of bone replaced, and the wound in the scalp united.

The patient being in excellent condition, it was decided to at once explore the opposite hemisphere. Accordingly an opening was made over the centre of the right Rolandic fissure. A smaller trephine and the rongeur forceps were employed, and the thickened bone removed with comparatively little difficulty. The membranes were again found markedly adherent, and the apparently normal brain tissue bulged more strongly than before. On probing, nothing was found until the instrument was directed toward the base of the skull. Here, from one to one and one-half inch from the surface, was encountered a decidedly resisting mass, having apparently a definite outline. The grooved director was pressed steadily into this mass until it penetrated and dropped into a distinct cavity, from which there flowed out, alongside the instrument, a quantity of clear fluid. After tying and dividing a large meningeal vein which was in the way, the opening was enlarged by inserting a pair of hæmostatic forceps, and spreading the blades as the forceps were withdrawn. Several ounces of clear fluid escaped, and the bulging of the brain subsided, leaving a depression on its surface. A small drainage-tube was inserted and brought out through a hole in the flap, the button replaced, and the wound closed.

It was decided by those present that the cavity which had been discovered and drained was either a serous cyst or a cystically enlarged right ventricle. It is certain that the left ventricle was not enlarged, this possibility having been excluded by thorough exploration. That the cavity was not merely a normal ven-

[1] On Chorea, by C. B. Radcliffe, M.D., F.R.C.P. 1868.

tricle was shown by its situation, its size, and its firm wall. The probability is that the cavity was a cyst following a hemorrhage, due to the penetration of the brain by one or more shot.

The patient left the operating-table in excellent condition, his temperature being 99° F. and pulse good. During the following night he uttered occasional loud cries, and became so restless that shackles had to be used. His temperature mounted to 101° F., but fell to normal by morning. The next night the shackles were again employed and the cries were repeated. On August 24th, the dressings, which were saturated with serous fluid tinged with blood, were renewed. On August 26th, the drainage-tube was removed, the discharge, which had been steadily decreasing, having almost ceased. The patient's condition gradually improved until it became better than before the operation. His mind grew clearer, and his headaches less frequent, until the latter finally disappeared. There was no improvement, however, in the paresis. During September 15th and 16th, five convulsions occurred, beginning in the left arm and extending to the rest of the body. He had no further trouble of this kind, however, while in the hospital, and was discharged on September 28, 1893.

The patient was seen again about nine months after the operation. For five or six months he had remained free from headache. At the end of that time he began to be annoyed by pain near the bregma, not so severe, however, as formerly. This continued at intervals for two or three months and then ceased, no headaches having occurred during the last three weeks. His intellect was found much clearer—he spoke quite easily and quickly, and seemed to have the ordinary intelligence of his class. He had had occasional epileptic attacks, but they had not been so numerous as before, and not nearly so severe. The paresis of the left side had improved, but the hand still remained useless. Altogether, the man's condition was much better than before the operation. Six months later the patient was again heard from, and his condition found to be about the same, perhaps, as before he was operated upon, all benefit which he had derived from surgical interference, which was at first quite marked, having disappeared.

Case II.—A healthy, well-developed white man, between twenty and twenty-five years of age, was struck by a limb of a falling tree, and suffered a compound fracture of the skull. Fourteen months after the injury, on March 12, 1894, he was admitted to Christ's Hospital in Cincinnati. A puckered scar indicated the seat of the fracture. The depression, which was considerable, was about an inch in length by two-thirds of an inch in width, and lay along the right parietal ridge just in front of a perpendicular line passing through the external auditory meatus.

Since the accident epilepsy had set in. The fits had neither been numerous nor close together, but had increased in severity. One occurred in September, one in December, and one in February. They were accompanied with loss of consciousness, and lasted about half an hour. They were preceded by contracture of the fingers of the left hand and a "sick feeling." Headaches had been frequent and annoying, and memory had suffered considerably. The entire left side of the body was somewhat weaker than the right, although the patient could handle himself fairly well. This weakness had been preceded by twitchings of the muscles, and then complete, but temporary, paralysis. The left side of the face was almost entirely paralyzed, so that the corner of the mouth could not be drawn back, and the tongue was much deflected.

An operation was made on March 14, 1894, chloroform being used as an anæsthetic. The fracture was exposed by a large horseshoe flap, and a button of bone removed with an inch trephine; after which the rongeur forceps were freely employed. The depressed bone was much thickened, roughened on its under surface, and adherent to the dura. When the dura was opened by a semicircular incision, beneath and adherent to it was found a yellowish, puckered mass, the size of the last joint of the thumb, merging into the surrounding substance of the brain. This proved to be partly fibrous tissue, and mostly remnants of an old blood-clot. There was no cyst. The cicatrix and a small portion of adherent membranes were carefully dissected out with scissors, leaving a cavity in which one could place lengthwise the last joint of the thumb. Hemorrhage was slight. In closing the wound, the dura could not be completely reunited, an opening the size of a finger-nail remaining. A drainage-tube was brought out through a special incision in the flap. The bone which had been removed was not replaced. Recovery from the operation was uneventful.

Owing to a free discharge of bloody cerebro-spinal fluid from the wound, necessitating renewal of the dressings, the drainage-tube was not removed until the fourth day. As the edges of the wound seemed united, the stitches were also taken out. This proved to be a mistake, as one end of the incision gaped considerably, requiring the re-insertion of one or two sutures. On the third day after the operation, a slight convulsion occurred, but was not followed by others. The headache disappeared at once and did not return; while the patient's memory gradually improved, until he considered it as good as before he was injured. The facial paralysis disappeared quite rapidly, so that in a week it was much better; and when the patient was discharged on April 14, 1894, only a trace remained; he could whistle easily. The weakness of the left side had also markedly improved; the muscles, the patient says, had grown larger and firmer. The tongue had lost its deflection. Constipation had given place to regularity of the bowels. In July, 1894, his condition remained unchanged. On February 26, 1895, nearly a year after the operation, the patient was again heard from. He had had no convulsions since July 8, 1894, the paralysis of the face had still further improved, while the hemiparesis had all but disappeared. The headaches had ceased, and memory was as good as it had ever been. Sufficient time has not elapsed to justify an ultimate prognosis, but so far the man's condition is decidedly improved.

When operative surgery of the brain is viewed as a whole, it impresses itself upon the observer that the most important point is surgical cleanliness. The brain will bear an astonishing amount of rough handling without serious consequences, providing that inflammation does not occur; and inflammation, as has been thoroughly established, is due to infection with micro-organisms. We may probe the brain in various directions, remove large portions of it, tap its ventricles, compress it, bruise it—in fact, there is no reason why we should not even sandpaper it, if it were desirable—without danger to life, providing only that we keep it clean. Consider the amount of bruising and laceration that may result from depressed fractures and bullet-wounds, and yet the patients often get well. The organ can even recover itself with facility after the removal of a blood-clot which has compressed an entire hemisphere. But if infection once take place, especially infection of the meninges, the patient's chances are poor indeed. Hence, as far as operative technique is concerned, nothing is so important as the prevention of infection. Whether we chisel out bone-flaps or employ the trephine; whether we replace the bone or leave the opening free; whether we divide the dura in a cross or in a semicircle; whether we explore in this direction or in that, or use one instrument or another—these are all minor considerations compared with the vital question of the prevention of inflammation. We should take care to do our patient no harm, even if we do him little good.

The subject is of such importance that one is justi-

fied in saying, I think, that, except in cases of absolute and immediate necessity, no one should open the skull, and particularly the dura, without being thoroughly familiar with all the details of surgical cleanliness, and without being prepared to carry them out with exactness.

The patient's head should be completely shaved and sterilized several days, if possible, before the operation, and protected by a sterilized cap or bandage. If a beard is present it should be removed, at least on the cheeks. If the seat of the proposed operation is on the anterior portion of the cranium the eyebrows should be shaved. It is very difficult to sterilize the beard and eyebrows, and in operating they may easily be touched by the operator's hands or instruments, and thus cause infection.

The head should be thoroughly scrubbed with warm soapsuds and a good brush, carefully cleaning out any old puckered scar which may be present. Such scars are dangerous, as they occupy the exact field of operation. Then vigorous scrubbing and douching with alcohol or ether, by means of a bunch of sterilized gauze. This is to remove any remaining oily substance which might interfere with the action of the antiseptic. Then follows another good scrubbing with a solution of bichloride of mercury of a strength of 1 to 1,000, or better 1 to 500. These several scrubbings must be more than mere formal wettings of the skin—they must represent an intelligent endeavor to remove and kill the micro-organisms which have not only adhered to the scalp, but have worked themselves in among the superficial epithelial cells and into various minute depressions. One should bear in mind that the skin comes in constant contact with the wound-secretions, so that germs have ample time to multiply and produce mischief. I believe that infection comes as often from the imperfectly cleansed skin of the patient as it does from instruments or even from the hands of the operator. After sterilization, the scalp should be covered with a layer of gauze or cotton wet in 1 to 1,000 bichloride-solution—and protected by a dry dressing. A wet towel, which is so often used, does not form a satisfactory dressing because it cannot be so perfectly fitted to the head.

A few hours before the operation, the scalp should again be sterilized; and not only the scalp, but the ears, neck, sides of the face, and forehead, and the face itself carefully washed. It is of no small importance to clean the ears without and within. Sometimes an ear must be included in the dressings; and, at least, they are apt to come in contact with hands, instruments, or sutures. If the ears, face, and eyebrows have not, for any reason, been properly attended to, danger may be avoided by catching a sterilized cloth about the head with a rubber band, and permitting the cloth to fall downward over the neck, ears, and face as far as the nose. If this band is heavy enough and tight enough, it will also control hemorrhage from the arteries of the scalp. There is generally considerable oozing of blood and cerebro-spinal fluid after an operation upon the brain, especially if the patient should vomit following the anæsthetic; hence it is best in most cases to use a drainage-tube; which should not be brought out through the incision, but through a special opening in the flap. The tube can be removed in a day or so.

The dressing of the wound is of importance. It has been sufficiently demonstrated that dryness is a prime factor in the prevention of germ-growth. The dressings should not only be perfectly dry in themselves, but should be so arranged as to facilitate rapid evaporation of the moisture which they absorb. They should cover as much surface as possible; and be of considerable thickness, to guard against the ready soaking through of fluids from the wound. The best dressing, I think, is arranged in this way: First, a large quantity of gauze, which should not be neatly and compactly folded, as is often done, but loosely fluffed up. Gauze absorbs more evenly when used in this way, and permits of more rapid evaporation. Over this is placed a moderately thick layer of sterilized cotton. It should be remembered that cotton is not used so much for absorptive purposes as for protection from germs, and hence it should cover in all the gauze, and come everywhere in contact with the surrounding skin. The comparative absorptive powers of cotton and gauze may frequently be noticed: fluids soak more or less directly through cotton, while they spread throughout a mass of gauze before appearing on its surface.

Some advise covering in the entire dressing with a sheet of rubber dam (see the "American Text-book of Surgery"). This is not wise, as it checks evaporation and keeps the dressing moist. For the same reason it is better not to use a starch-bandage, or even a common muslin roller, for the final covering, but a bandage of simple gauze.

If the discharge soak through, or appear at the edges of the dressing, a new dressing must be applied at once, as micro-organisms rapidly grow into the moist material. When the dressing becomes stained through it is a mistake to cover it up with more cotton. The danger is not removed, but only concealed; for we can rest assured that infection has occurred as soon as the staining manifests itself.

It is practically immaterial whether one uses plain gauze, iodoform gauze, or that impregnated with various antiseptics; only it must be dry and surgically clean. Plain and freshly sterilized gauze is, I think, the most reliable and satisfactory. Where a steam sterilizer cannot be obtained, gauze and cotton may be easily prepared by placing them, very loosely packed, in a pan in the oven of an ordinary cooking-stove. When the cotton begins to brown on the surface, the material is sterilized.

Time will not permit me to dwell upon the care with which hands, instruments, sutures, etc., must be rendered free from infecting micro-organisms, nor upon the precautions which must be employed to preserve perfect cleanliness after it has once been obtained. These are all points, however, which must be thoroughly mastered before operative work upon the brain should be attempted.

URETHROSCOPY IN CHRONIC URETHRITIS.[1]

By FERD. C. VALENTINE, M.D.,

NEW YORK.

GENITO-URINARY SURGEON WEST SIDE GERMAN DISPENSARY, ETC.

It would be absurd to hold that all cases of chronic urethritis must necessarily be treated by the specialist. The majority can be successfully managed by the general practitioner, who, however, as a rule, cannot devote the time necessary for that careful individualization which each case requires. Furthermore, the general practitioner can hardly be expected to provide himself with cumbersome and expensive apparatus and instruments, for which he has but occasional use.

The many pathological elements upon which chronic urethritis may depend, need not now be discussed. This paper's object will be subserved in mentioning the conditions found by urethral endoscopy, without which no chronic urethritis can be intelligently treated. Time was when every chronic urethritis was deemed dependent upon a stricture. The urethra was unmercifully slashed: true enough, with good effect in many cases, but it needed the superior skill of an Otis to have genuine cicatricial warrant for such procedure.

The three casts of normal urethræ I have the pleasure of showing, evince the fact that nature never intended the urethra to be a tube of equal calibre

[1] Read before the Harlem Medical Association, June 5, 1895.

throughout its entire length. On the contrary, there are so many variations that it is absolutely impossible to even suggest an average diameter for any one case. But this is not very important for the present consideration, save in the sense that to judge intelligently of what we find in the urethra, we must know that at almost every hair's-breadth its calibre differs materially.

We know to-day that chronic urethritis does not at all necessarily depend upon stricture; nor need it manifest itself in *goutte-militaire*, or even slight agglutination of the lips of the meatus. Indeed, a chronic urethritis can exist with no further manifestation than clap-filaments, whose presence should be a warning to many men. To others these "Tripper-fäden" are a source of grief, with all the usual mental concomitants of sexual diseases. Early this year, in a paper on "Gonorrhœal Hypochondriasis," read before the Berlin Anglo-American Medical Society, I went so far as to claim for chronic gonorrhœa the possible ability to evoke insanity, and suggested the advisability of unexplained suicides being examined for the presence of inflammatory foci or gonococci long retained within urethral crypts, glands, or follicles. Subsequent investigation, study, and thought have convinced me that the possibility is not so remote as might at first appear. Aside, then, of local effects and readiness for contagion, chronic urethritis merits consideration for its direct influence upon the patient's sensorium commune.

The need, therefore, of most thorough searching of the urethra for a diseased condition is too evident for discussion. Tactile exploration, so useful when grosser constrictions are the cause, is necessarily limited in its revelations. Considering that most diseased processes take place beneath the mucous membrane, they are entirely obscured from what the sound can communicate to even the most sensitive touch. This fact, that the vast majority of pathological processes in the urethra are situated beneath the mucosa, has been used as an argument against urethroscopy. It has been held that their submucous location necessarily excludes them from visual detection. Were this invariably true, we would have to depend exclusively upon the sound for diagnostic purposes. How often it can yield unsatisfactory results need not be recited. Our other alternative, then, without urethroscopy, would be to treat chronic urethritis empirically. This, to paraphrase an old adage, would be to literally "thrust into a urethra of which we know nothing, remedies of whose effect we consequently can know less."

In a measure, the unavailability of urethroscopy holds good when reflected or projected light is used. It is in this that I differ from my friend, W. K. Otis, whose most ingenious aero-urethroscope offers everything that can be desired in that class of instruments. But the instrument which I shall have the privilege of demonstrating on the patients whom I brought here for that purpose, carries the light into the urethra, to each and every point it may be desirable to examine. This, the Nitze-Oberländer urethroscope, not only satisfies the physical demand for visual acuity by the greatest intensity of illumination, but it also renders much of the lower part of the urethra translucent. Thus it can aid the experienced eye in at least locating a covered diseased process.

This by no means implies that every chronic urethritis depends upon a submucous diseased spot, which need but be cauterized, incised, or excised to cure the infection. On the contrary, there are many other conditions which the urethroscope exposes to sight. These require as much study as do the pathological changes which are found in other parts of the body. Thus we may have variations in the color of the mucous membrane, loss of normal striation, increase or diminution of the normal urethral folds, gaping glands, and numerous other conditions. All of these and combinations of them indicate various etiological factors. Epithelial denudations, ulcers, circumscribed or general diseased conditions of a catarrhal or specific character, neoplasms, etc., are discoverable only by means of the urethroscope.

Oberländer, if he deserved no other credit, merits immortalization for his industrious studies of the urethra and devising methods of treatment for chronic urethritis. Incidentally, it may be mentioned here that he was the first to diagnose carcinoma of the urethra by means of the endoscope.

Oberländer found an active coadjutor in Kollmann, who did, and is doing, much original work in urethroscopy. At some future time I hope to show photographs taken by him of the urethra. These demonstrate that chronic urethritis, which is only a generic term, is of sufficiently varying origin to merit all that Oberländer, Kollmann, and others have written on the subject.

In this connection it must not be forgotten that the urethroscope often proves useful in finding the hidden lumen of severe strictures—another condition provocative of chronic urethritis.

It is certainly true that the mere presence of the urethroscopic tube can produce apparent anæmias or hyperæmias. To the inexperienced eye they may convey pathological changes where none exist. But study and practice do away with this source of error. They also teach the selection of the proper calibre of tube for each urethra, and so holding it that the examined parts are rendered neither paler nor darker than in reality they are.

We are met, then, by three self-evident propositions: 1, Chronic urethritis is a generic term, covering many diseases; 2, most of these diseases cannot be discovered by intra-urethral touch or by external manifestations; 3, they can be located, studied, and treated only through the urethroscope.

A discussion of the various kinds of urethroscopes would lead beyond the purposes of this paper. In one, presented by me to the American Medical Association on May 7, 1895, they were described. Careful examination of all causes me to advocate the Nitze-Oberländer urethroscope, whose intensity of direct illumination compensates fully for whatever may at first appear cumbersome in the apparatus.

The one I have the privilege of showing now, and which I will demonstrate in use on the patients here for the purpose, is naturally not of the dimensions which I would advise the general practitioner to acquire. The smaller forms amply suffice for all general purposes. They consist essentially of a small accumulator, connected through a simple rheostat with wires which conduct to the light-carrier. This light-carrier has a tube which carries water to it, and another which carries water from it. By means of this flow, the uncovered wire, made incandescent, is kept cold, no matter how long it rests in the urethra. This apparatus, in its simpler or more complex forms, is made by Heynemann, of Leipzig. The form I use is one intended for specialists.

I abstain from recording a more detailed description of the instrument, as it is soon to be published in an article, in English, on Urethroscopy, by Wossidlo, of Berlin. For the same reason I do not now mention anything of the technique of urethroscopy; furthermore, it will be evident to those to whom I have the pleasure of showing the very few and simple manipulations required.

The appearance of the urethra varies in accord with the region examined, as well as with the pathological conditions that may prevail. Oberländer, Kollmann, Posner, Grünfeld, Burckhardt, have described these in their works, whose study cannot be too highly recommended.

As vastly different as are the pathological conditions which cause and sustain chronic urethritis, so varying must necessarily the treatment be. Shall we inject,

irrigate, or cauterize; shall we incise strictures or diseased glands; shall we perform a species of massage of the entire urethra by Oberländer's or Kollmann's modified Otis dilators; shall we instill with the Guyon or Ultzmann syringes; shall we use Gschirrhakl's brush or Winternitz's psychrophor; shall we dilate with sounds, or shall we leave the urethra alone and obtain relief by constitutional treatment?

These questions can be answered only after that close individualization, which nothing but the urethroscope can give. It would be folly to assert that no cases have recovered without urethroscopy. In some, accident has given success to crass empiricism; but these could have been intelligently treated and more quickly cured, if they had been properly examined. It is, therefore, evident that no attempt should ever be made to treat chronic urethritis until the practitioner has ascertained what the diseased condition is and where it is located. Nothing except urethroscopy will furnish these absolute essentials.

242 West Forty-third Street.

INSOLATION OR THERMOPLEGIA: A CLINICAL STUDY.

By F. W. ANTONINUS FABRICIUS, M.D.,

ex-house physician of bellevue hospital, new york city.

Insolation or thermoplegia comprises various explosive phenomena originating in the central nervous system as the result of prolonged exposure to a high temperature and an accumulation of toxic products in the blood. Violent muscular exercise and severe mental strain are noted predisposing factors.

Clinically, three distinct varieties are recognized, each form demanding special treatment modified in accordance with the intensity of the attack and the condition of the individual.

1. **Anæmic Form.**—This type, better known under the name of heat exhaustion, generally affects debilitated subjects with a high-strung nervous system and low resisting power. The onset is the least sudden of the three classes of cases, presenting a prodromal stage of variable duration. The symptoms are characteristic of cardiac syncope, mental depression, dizziness, headache, great prostration, and at times nausea and vomiting; the patient sinks to the ground utterly exhausted. Consciousness may be preserved for some time or not lost at all; usually, however, syncope supervenes, rapidly deepening into coma. Countenance is pale, eyes are half closed, pupils widely dilated, and the muscles completely relaxed. The skin is cool and clammy, the pulse accelerated and feeble, later on irregular, respirations are sighing and increased in frequency. Superficial reflexes are for the time abolished, deep continue unaffected. The temperature is below the normal, ranging from 97° to 95° F. per rectum. Death may result immediately from cardiac paralysis, or later on from asthenia; in one instance an epileptiform convulsion terminated the scene.

Treatment.—In mild cases with transient syncope rest alone is indicated; the severer forms of collapse, however, call for immediate stimulation to support the exhausted heart. Remove patient to a cool, shady place, with the head lower than the knees and inject subcutaneously twenty minims of aromatic spirits of ammonia, to be followed by

℞ Strychn. sulph ..... gr. $\frac{1}{30}$
Atropin. sulph..... gr. $\frac{1}{150}$
Glonoin..... gr. $\frac{1}{2}$
M. f. hypo. S.: one dose.

If the heart responds put patient to bed and apply a hot pack, with hot-water bottles to the feet and a cold cloth around the head. It is not advisable to allow patient to remain in the pack over half an hour, for the temperature might suddenly jump to the other extreme, rendering the prognosis very unfavorable. Sponging the body with hot water containing one-third of alcohol is a very successful method of administering warmth and stimulating capillary circulation. Should the temperature fail to rise, a quart of a one per cent. solution of sodium chloride at a temperature of 105° F. may be injected per rectum. Owing to the irritable condition of the gastric mucous membrane alimentation is to be carried on by nutritive enemata.

2. **Congestive Form.**—In the second or congestive variety the onset is more precipitate and the prodromal stage of shorter duration. The individual is suddenly seized with violent throbbing pains in the head and back of the neck, vertigo, tinnitus aurium, and marked muscular weakness, dropping senseless to the ground. The face is flushed, conjunctivæ are injected, pupils dilated; pulse is accelerated and of rather high tension; respirations are quite deep and rapid. Skin is congested, usually moist. The temperature is elevated, rarely, though, over 103° to 104° F. In favorable cases this stage of coma subsides in two to three hours, leaving the patient with often violent neuralgic pains and headaches, slowly regaining his former state of health, but sometimes continuing mentally enfeebled.

Treatment.—Applications of cold, if the temperature is 103° F. or over, in the form of sponge bath or wet pack. A very serviceable apparatus for the administration of cold baths, particularly in hospital and fever practice, has been devised by Dr. H. M. Biggs, of Bellevue Hospital, and has since been adopted by the New York Board of Health. It combines all the advantages of the plunge bath with a minimum disturbance to the patient, who is simply turned from side to side in his bed while the apparatus is adjusted.

Free catharsis should be encouraged as much as possible, either by enemata of glycerine and ox-gall, each ℥ j., or gr. ⅛ of elaterin given by mouth. Venesection may be of service in some cases, especially if the patient is robust and full-blooded; this may aid in preventing pulmonary complications, which are very liable to occur in this type of the disease. If, on the contrary, the heart-power fails, then active stimulation must be resorted to. In the after-treatment phenacetin, bromide, and chloral will be found of service in relieving headache and insomnia.

3. While the preceding forms are met with at all times during the year, the third or apoplectic type is rarely, if ever, seen except during midsummer with high external heat and great accumulation of moisture. Persons living in unhealthy districts, and those undergoing violent exertions, such as stokers on tropical steamers, workers in gas-houses, soldiers on forced marches, etc., easily succumb to this disease.

The onset is invariably abrupt, the patient falling to the ground as if struck by lightning. Consciousness is lost almost immediately; countenance is deeply congested, almost cyanotic; the veins of the forehead are engorged, and stand out prominently; the features are entirely relaxed and devoid of expression; eyes are wide open and fixed; pupils show marked contraction; skin is dry and burning hot to the touch and appears mottled in places; the pulse is accelerated, full, and bounding; arteries pulsating forcibly against the examining finger; respirations are increased in frequency and quite deep; temperature ranges from 106° to 110° F., or even higher, in one case rectal temperature was found to be 110.8° F. Coma is very profound; muscles are completely relaxed; cutaneous reflexes lost; deep reflexes increased. We find paralysis of the sphincters, involuntary passages of urine and fæces, the latter usually of a light yellow color, a diarrhœic consistency, and a peculiar sickening odor. Vomiting early in the attack was observed only infrequently.

This type is most fatal; death resulting from apnœa. The coma lasts anywhere from three to twelve hours.

In one instance, seen in 1892, patient remained comatose for sixty-two hours and recovered eventually. The chief source of danger is found in the hyperpyrexia; if not speedily checked acute cerebral œdema and dangerous meningeal congestion will soon place the patient in a critical state. In severe cases grave symptoms, indicative of rapidly progressing changes in the gray matter, become apparent; just what these changes are has not been definitely settled. Owing to the high temperature the elementary constituents of the blood must undergo important transformations, and so will all the other tissues in immediate contact with it. The soft, yielding, nervous centres suffer most. Following the sudden rise in temperature, and the highly increased blood-pressure, along with certain hæmic changes, degenerative processes take place in the vessels, favoring a transudation of the serum into the parenchyma of the nerve-tissues and their lymph spaces, offering an obstruction to the return flow of blood, resulting in venous hyperæmia. The ganglion cells themselves probably undergo changes in addition to the above-mentioned transient nutritive disturbances; there possibly occurs a partial or complete coagulation of the protoplasm in the cells, with a secondary disintegration of the myeline in the nerve-fibres, induced by the intense degree of thermic energy. If these pathological changes advance beyond a certain point, death must inevitably result, for regeneration of the nerve elements does not occur; this may explain certain sequelæ during the convalescent stage, particularly mental derangements, as dementia and imbecility, which presuppose a destructive process in the brain.

Usually the patient's condition changes after two to four hours; either consciousness partially returns and he recovers, or—and this is more frequent—the symptoms increase in severity, nearing a fatal termination. Facial paralysis develops, interfering with respiration, during which act lips are sucked in and puffed out, breathing becomes labored and stertorous, pulse gradually loses in volume and tension, and gains in rapidity. In the course of eight to ten hours rigidity of the back of the neck and contractures of arms and legs appear, indicating spinal involvement; these cases were invariably fatal. The temperature oscillates between 106° to 109° F., influenced largely by hydrotherapeutic measures. It may remain continually high or remit three, even five, degrees, to rise again in two to three hours; a decided elevation just before dissolution is common. The urine contains a variable amount of albumin, resulting either from a pre-existing nephritis, or an acute parenchymatous degeneration of the kidneys; in one case hæmoglobinuria was present. In three cases seen in 1893, at Havana, Cuba, punctiform hemorrhages appeared in the conjunctiva, in the subcutaneous tissues of the eyelids, abdomen, and feet.

Death occurring early results from cardiac paralysis or apnœa: after two to three days from cerebral œdema or secondary meningitis; later on from parenchymatous inflammations. Uncomplicated recoveries are said to be infrequent, insanity constituting a common and dreaded sequel.

Treatment.—Everything depends on the speed by which the high temperature is brought under control. Loosen the clothing and remove the patient to a cool, shady place, where there is free access of air; strip him of all clothing and apply cold in some form. A most efficient method is found in the garden-hose, douching the body thoroughly all over for twenty to thirty minutes till a decided impression is made on the temperature, which usually falls then to 105° or 104° F. The stream of water strikes the body with considerable force, exerting a great deal of friction, thereby stimulating to a high degree the cutaneous capillary circulation and exposing in this manner more blood to the cooling influence of water. A hypodermic injection should now be given of—℞. Tinct. strophanth. ♏x.; tinct. acon. rad., ♏ij.; glonoin, gr. $\frac{1}{50}$. Mix, and repeat in two hours.

The douche may be employed again, if temperature calls for it, in one to two hours, but it is preferable to substitute the plunge-bath containing large pieces of ice. While one attendant supports head, two others should rapidly and thoroughly massage the whole body to bring the blood from the overheated organs to the surface. An ice-cap is to be applied to the head, or better, a piece of ice rubbed over it and neck. The temperature is to be recorded every ten minutes, with the pulse and respirations. Shock need not be dreaded if above directions are carried out conscientiously, particularly in regard to friction, which constitutes an important vascular stimulant. When the temperature approaches 103° F., a sudden change takes place, the patient becomes very restless and makes unsuccessful efforts to get up, he puffs and groans, respirations are accelerated, while the pulse drops from 190–200 down to 150–140 without losing in tension. The skin assumes a healthy red hue, the pupils suddenly dilate, and explosive vomiting of enormous quantities of a greenish-brown fluid occurs, sometimes projected over six feet from the body; it was found to be unusually rich in urea, with an admixture of altered red blood-cells, the reaction was acid. Sensibility may now return, but this is infrequent; the before-mentioned phenomena are purely reflex. As soon as thermometer indicates a fall below 103.5°–102° F., patient is to be removed from tub and placed on a bed, covered with a rubber blanket, and is then enveloped in a cold, wet sheet, moistened occasionally with ice-water. Should, notwithstanding this, the temperature rise again, the plunge-bath may be repeated, or the bed-bath substituted. Enemata of cold water, temperature of 50° F., combined with gastric lavage, exert a powerful stimulating influence. The water should be allowed to run in and out slowly, and its gain in temperature noted.

If the individual is free from organic disease and strong, phlebotomy must be performed. It aids in reducing temperature, overcomes meningeal congestion, and by lessening arterial tension may abort an impending cerebral œdema, diminishing the liabilities to serious complications. Fourteen ounces of blood may be removed with perfect safety; in one case a corresponding amount of Billroth's solution, at a temperature of 58° F., was allowed to escape under low pressure through a hypodermic needle into circulation through the same opening in the vein, effecting a drop of two and a half degrees in the rectal temperature. Subcutaneous injections of carbamide of quinine, antipyrine, and salicylic acid were found useful in those cases when prolonged application of cold did not materially reduce the temperature—antipyrine in five-grain doses is most reliable. The judicious administration of tincture of aconit. rad., ♏ss. every twenty minutes, is followed by the happiest results in relieving the dry, hot skin, acting as a mild diaphoretic and nervo-vascular sedative; it should be discontinued, when a marked impression has been made on the pulse. Active diaphoresis may be induced by pilocarpine administered subcutaneously; by mouth, gtt. iij. of ol. tiglii are to be given to thoroughly cleanse intestinal tract. Hypodermic injections of fifteen-grain doses of magnes. sulphat. failed to effect evacuation of the bowels. Venesection may be repeated in apoplectic persons, but it is wiser to substitute any of the above-mentioned vascular sedatives. A fly-blister to the back of the neck is sometimes useful. In all cases where temperature ranges above 107° F. the hair should be cut close to the scalp and an ice-cap applied; or still better, tie a large abdominal ice-coil to the head and let ice-water circulate through it constantly. Fibrillarly twitchings of the muscles and severe convulsions invariably predict a fatal issue close at hand. Amyl nitrite to nostrils, or glonoin hypodermically, with inhalations of chloroform, may diminish their intensity, but

not remove the underlying condition. Morphine has been used, but is contraindicated from the marked meningeal hyperæmia it induces. Chloral and bromides are useless during the convulsion, but they may, given per rectum at the proper time, abort it. Chloral, fifteen grains, pot. brom., forty grains, administered per enema, when the fibrillary twitching commences, may be successful.

When patient regains consciousness temperature usually falls below normal, but alcoholic stimulants are rarely called for; on the contrary, they do harm by precipitating or augmenting meningitis. After one to two days a febrile reaction—a rise to 102° to 103° F.—is seen and may indicate meningeal involvement. Generally, however, it is of no vital importance. Should, however, meningitis set in, the prognosis is rendered very grave; it is therefore advisable to continue the use of the ice-cap or coil, and administer a cerebral sedative, such as bromides, ten grains t.i.d. The diet should be very light and cold, milk with Vichy, seltzer, or lime-water, iced lemonade, and a little claret well diluted. If the stomach rebels, rectal alimentation is called for. The severe throbbing headache and aching pains are best combated by counter-irritation and the coal-tar preparations. The bowels must be kept open by the free use of alkaline waters saturated with salts of magnesium and sodium. The room should be kept dark, but well aërated, and all active movements interdicted. The stage of convalescence is slow and tedious, and marked by the appearance of sequelæ of more or less significance. The brain is the last in recovering its former functional activity, if it does at all, and it is the duty of the physician to familiarize the patient's friends with the possibility of a permanent mental derangement at an earlier or later period. At best the individual will always be delicate and greatly susceptible to the influence of heat, and therefore he should be advised to live in a temperate, even climate.

NEW LAWS OF INTEREST TO PHYSICIANS.

By FREDERIC G. MATHER,

ALBANY, N. Y.

The recent Legislature passed a number of laws and amendments of interest to the medical profession. Among the most important amendments were those to the Public Health Law as follows: Providing that the State Board of Health appoint two of its members as a committee, whose particular duties shall be to carry out the provisions of the Public Health Law relating to tuberculosis in cattle, and such members so appointed shall be entitled to receive a salary of $250 per month and any necessary expenses, and they shall hold office for one year; such committee shall keep a complete record of all the work done, and submit monthly reports thereof to the State Board of Health. Providing that (in Section 145), the degree of bachelor or doctor of medicine shall not be conferred in this State before the candidate has filed with the institution conferring it the certificate of the regents, that three years before the date of the degree he has either graduated from a registered college or satisfactorily completed a full course in a registered academy or high school, or had a preliminary education considered and accepted by the regents as fully equivalent, or had passed regents' examinations, representing for degrees conferred in 1898, one year of academic work, for degrees conferred in 1899, two years of academic work, and for degrees conferred in 1900, a full high-school course. Dropping out (Section 153) the prohibition of using any title whatever which shall show or tend to show that the person so assuming or advertising the same is a practitioner of any of the branches of medicine, but still retaining the prohibition of the unauthorized use of M.D. Revising Article 9, by vesting the power of granting licenses to practise dentistry in a State Board of Dental Examiners and assimilating in that regard the licensing of dentists to the licensing of physicians, and also providing punishments for violation of the provisions of the law. Revising Article 10 by making more strict examinations for licenses to practise veterinary medicine and surgery. Section 184, requiring that every licensee of the State Board of Pharmacy who desires to continue the practise of his profession shall annually, within thirty days from the first day of November, pay to the secretary of said board a fee of $1, for which he shall receive a renewal of his license, which renewal shall be displayed with his license.

The following amendments to the Public Health Law did not pass: Section 207, allowing medical colleges or schools to use unclaimed cadavers from almshouses; same Section, providing as to cadavers, that it shall apply only to the counties of Onondaga, Oswego, Madison, Cortland, and to Auburn State Prison. These bills also did not pass: Providing that, in addition to the powers now conferred by law upon the State Board of Health, the board is empowered, and it shall be its duty upon receiving a fee therefor of $50, to cause an examination and analysis to be made, by a practical chemist, of any drug, medicine, or mixture of drugs, herbs, or medicines, commonly known as patent or proprietary medicines, and shall ascertain and determine whether the use of the same may or may not endanger the public health, and it shall not be lawful for any person or corporation to sell, or offer for sale, any drug, medicine, or mixture not prescribed by a regular physician, unless the same shall have been so examined and approved and certified in writing as not dangerous to the public health by the State Board of Health. Amending the State Board of Pharmacy Law of 1884 so that any person who had three years' experience in the practice of pharmacy previous to January 1, 1884, shall be entitled to be licensed as a pharmacist, and if the State Board of Pharmacy shall refuse to grant such license, upon application duly made by such person to the secretary of said board, and the payment of the license fee required by law, such person may, on fifteen days' notice to the secretary of such board, apply to the Supreme Court, at a special term, in the district in which such applicant resides, for an order directing such board to issue such license. Abolishing the office of coroner, in accordance with the revised Constitution, and providing for the performance of the duties now performed by coroners. Amending the coroners' law of 1875, so that the board of supervisors shall, at its next annual meeting, and from time to time thereafter, fix the compensation of the coroners in Erie County at $2,500 per year for all services done and performed by them, except when acting as or in the place of the sheriff of said county, and which compensation shall not, in the case of a coroner residing in the city of Buffalo, at the time of his election, and during the term of office, exceed the sum of $3,000, and not exceeding two in number, and of any coroner not residing in the city of Buffalo, at the time of his election, shall not exceed the sum of $500 per annum, which compensation shall not be increased during the term of office of such coroner, and shall be in lieu of all fees or mileage for such services. Amending the county law so that no person shall hereafter be eligible to the office of coroner who is not an attorney and counsellor-at-law, but the holding of such office shall not act to prohibit him from practising at any court, except in relation to any case which may have been before him as a coroner. Amending Section 390 of the Penal Code so as to make guilty of a misdemeanor any person who, in various ways, pollutes any public water-supply. Authorizing the Superintendent of State Prisons to use in the several prisons of the State the double-chloride-of-gold treatment for the cure of liquor, opium, morphine, cocaine, and tobacco diseases, and to negotiate for and purchase such

medicines prepared under recognized double-chloride-of-gold formulas as in his judgment he may deem advisable for the purpose of administering such treatment, and in carrying out the provisions of this the superintendent may cause one or more of the prison physicians to be instructed in the administering of the remedies prescribed, and the treatment of the diseases enumerated. Repealing the law of 1893 relative to the vaccination of school children.

The Code of Civil Procedure was amended so as to exempt from jury duty, the same as a physician, a duly registered veterinary surgeon actually engaged in his profession as a means of livelihood. The sum of $100,000 was appropriated for the purpose of constructing and equipping suitable buildings for the State Veterinary College at Cornell University, but no part of such moneys shall be expended until plans and specifications for the construction and equipment of such buildings and the location thereof shall have been approved by the Commissioner of Agriculture, nor until the Comptroller shall have certified that, in his judgment, the expenses of the completion and equipment of such buildings, in accordance with such plans and specifications, will not exceed the amount of such appropriation, and such buildings and equipment shall be the property of the State.

A law was passed regulating and restraining the practice of midwifery in Niagara County by others than legally authorized physicians. The county judge of that county is authorized to appoint a board of examiners in midwifery, to consist of five members, who shall have been licensed to practise physics and surgery in this State, and thereafter as often as any vacancy shall occur in said board, said county judge shall, by a like order, fill such vacancy. This board is to issue certificates, and anyone practising without a certificate on conviction thereof shall be fined not less than $50, nor more than $100, and shall forfeit any certificate granted under the act. A similar law was passed for Rochester, allowing the mayor to appoint a board of three examiners; but an amendment to the law for Erie County failed, providing that on and after July 1, 1895, the county judge of Erie County shall appoint a board of examiners in midwifery, to consist of nine instead of five members, who shall have been licensed to practise physics and surgery in this State, and who shall have been in active practice for at least two years; three of said members shall be designated by said county judge to hold office for one year; three of said members to hold office for two years, and three of said members to hold office for three years. Annually thereafter the said county judge shall designate three physicians to hold office as members of said board for a term of three years.

The new Membership Corporations Law, from the Statutory Revision Commission, provides that five or more persons may become a corporation for the purpose of erecting, establishing, or maintaining a hospital, infirmary, or home for invalids, aged or indigent persons, by making, acknowledging, and filling a certificate, stating the particular object for which the corporation is to be formed; the name of the proposed corporation; the town, village, or city in which its principal office is to be located; the number of directors, not less than three nor more than thirty; the names and places of residence of the persons to be its directors until its first annual meeting, and the time for holding its annual meetings. Such certificate may also specify the qualification of members of the corporation with respect to their adherence or non-adherence to a particular school or theory of medical or surgical treatment, and the systems of medical practice or treatment to be used or applied in such hospital, infirmary, dispensary, or home. Such certificate shall not be filed without the written approval, indorsed thereupon or annexed thereto, of the State Board of Charities, and of a justice of the supreme court of the district in which the principal office or place of business of such corporation shall be located. On filing such certificate, in pursuance of law, the signers thereof, their associates and successors, shall be a corporation, in accordance with the provisions of such certificate.

A new law "to protect human life" provides that all hospital buildings used for general hospital purposes, or hospitals or asylums for the insane, or any hospital buildings that are more than two stories high, shall have properly constructed iron stairways on the outside thereof, with suitable doorways leading thereto from each story above the first, for use in case of fire. It shall be the duty of the trustees, managers, owners, or proprietors of such hospitals or asylums to cause such stairways to be constructed and maintained. If the trustees or owners of any hospital, except those owned and maintained by a city, a county, or the State, shall fail to provide such stairways before the first day of October, 1896, then the local authorities shall proceed to erect such stairways, and the cost thereof may be recovered by an action at law from the property of said hospital. The district attorney of each county is charged with the execution of this statute, except in the case of hospitals erected or maintained by the State, city, or by a county. This law is to take effect on the first day of October, 1895. The provisions do not apply to any institution in the city and county of New York, or the county of Kings, which the fire marshal of said city or county shall certify in writing to be fireproof to an extent which will not require the appliances and fixtures provided for. In every other county such certificate shall be made by the district attorney of the county. The certificate exempting institutions in any county from the operations of this law shall be filed during the month of January in each year.

A charter was granted to St. Joseph's Hospital, in Syracuse; and the charter of Kingston was amended so that $2,500 can be appropriated yearly to the Kingston City Hospital. The name of the Bedford Dispensary, in Brooklyn, was changed to the Bedford Dispensary and Hospital. The charter of the Brooklyn Eye and Ear Hospital was amended so that the directors shall be not less than eleven nor more than nineteen. In Oswego a charter was given to the "Doctor Mary V. Lee Fund to Aid Worthy Students." The board of trustees of the Clifton Springs Sanitarium Company was authorized to issue bonds not to exceed $100,000, and mortgage the trust property to raise money to pay the cost of completing the new sanitarium building. Authority was given to the Board of Commissioners of the Washington Park, Albany, to convey or lease a plot of ground for the purpose, and to be used for the erection thereon, of the Bender Hygienic Laboratory, and the laboratory has been incorporated. A charter was given to the Pedic Society of the State of New York.

In New York City the Consolidation Act was amended so as to provide for the making and use of diphtheria antitoxin and other antitoxins, and to establish a fund in relation thereto. A charter was granted to the Hospital for Scarlet Fever and Diphtheria Patients, with Louisa F. Minturn, F. Augustus Schermerhorn, Paul Tuckerman, James J. Higginson, Frederic De P. Foster, John Winters Brannan, M.D., Cleveland Dodge, T. Mitchell Prudden, M.D., Alvah H. Doty, M.D., and George F. Crane, as the incorporators. Another new law provides that overseers of the poor or other officers having charge of the dispensation of public charity in the several counties of this State shall hereafter send to the Pasteur Institute, in the city of New York, all persons duly certified by regular physicians to have been bitten by rabid animals or otherwise put in danger of infection with rabies. The transportation of such persons, with necessary attendant or attendants, to and from the city of New York, shall be a charge upon the counties in which they reside. The sustenance, nursing, and

preventive treatment of such persons, for the time adjudged necessary, shall be provided by the Pasteur Institute. The sum of $6,000 was appropriated to the Pasteur Institute as a full equivalent for the services named in the law and conditions imposed thereby. The Pasteur Institute shall be at all times open to the inspection of the Governor and of the State Board of Health, or of the accredited representative of either, and shall annually, on or before the fifteenth of January of each year make its report to the Legislature.

Other amendments to the Consolidation Act were these: Allowing annual appropriations of $12,000 and $30,000, respectively, to the Society of the Lying-in-Hospital and to the New York Post-Graduate Medical School and Hospital; allowing to the New York Polyclinic Medical School and Hospital, for board, nursing, and medical or surgical aid and attendance, $1 per day for each needy and charity patient who occupies a bed in said hospital, and who receives such care, support, and maintenance, such payments not to exceed in the aggregrate $30,000 per annum; relative to coroners; exempting from taxation the property of the Northeastern Dispensary. Other laws were as follows: Amending the charter of St. John's Guild so that it may hold property, provided that the annual net income of the property, real and personal, of the corporation shall not exceed the amount authorized to be received and held by hospital corporations under the laws of the State; changing the corporate name of the New York Orthopedic Dispensary to the New York Orthopedic Dispensary and Hospital; extending permanently the charter of the College of Pharmacy of the City of New York, with Samuel W. Fairchild, Charles F. Chandler, George Massey, John R. Caswell, J. Niven Hegeman, Horatio N. Fraser, as incorporators, and allowing it to hold property not to exceed $1,000,000; exempting dispensaries from the payment of water assessments; authorizing and directing the Commissioners of the Sinking Fund of the City of New York, whenever required so to do by the Board of Estimate and Apportionment, to designate and set apart so much of Gouverneur Slip as will be requisite for the construction thereon of a building, the entire cost, expense, and equipment of which shall not exceed $200,000, for the purpose of providing suitable accommodations for a reception hospital for patients injured or taken suddenly ill in the lower east side of the city. The Governor refused to sign a charter for the Metropolitan Post-Graduate School of Medicine, with Timothy Field Allen, William Tod Helmuth, Arkell R. McMichael, Malcolm Leal, Charles Deady, Henry M. Dearborn, Wilfred George Fralick, James H. Schley, William H. Bishop, John W. Dowling, George T. Stewart, and Joseph M. Deuel, as the incorporators.

120 LANCASTER STREET.]

A Family Birthday.--Dr. W. A. Chamberlin, writing in the *Northwestern Lancet*, relates a curious coincidence in the dates of birth of three children of one family. The eldest child was born on April 3, 1882, the second on April 3, 1887, and the youngest on April 3, 1889, and all within three hours of 3 P.M.

A Penny-in-the-slot Doctor.—The English papers describe a new machine, figured in the likeness of a man, which is provided with slots corresponding to various parts of the body. If one has a headache he has only to insert a coin into the slot in the head, and the machine, after due consideration, hands out a prescription for the evil in question. The machines do not make up medicine, but the address of the nearest druggist is given. It only remains for some enterprising philanthropist to supply London with these machines, says *The Lancet*, and the relief to the overcrowded out-patient department of our hospitals would be marked.

Progress of Medical Science.

Perforation of the Diaphragm in Gastric Ulcer.—L. Pick, in reporting a new case, gives an analysis of all cases published in which ulcer of the stomach caused perforation of the diaphragm (*American Journal of the Medical Sciences*). In all, twenty-eight cases were discovered; but the author thinks that other cases, proved by autopsies, have been observed, and also that in certain cases of so-called idiopathic suppurative pleurisy or pericarditis gastric ulcer was the cause. (In regard to this, however, Biach has shown that in nine hundred and eighteen cases of pyopneumothorax only two were due to ulcer of the stomach.) According to Pick, perforation of a gastric ulcer into the thoracic cavity is twice as frequent as adhesion to and perforation of the anterior abdominal wall. The commonest outlet is in the pleura or lung, and affected the left pleura nine times, the left pleura and lung seven times, and the right pleura once. In the latter case the perforation was consecutive to subphrenic abscess. The pericardium was affected alone in six cases, and the pericardium and heart in four. In one case the mediastinum was affected, and in the author's case the anterior thoracic wall, with the formation of a tumor in that part. In twenty cases the perforation was direct, and in eight indirect, or following subphrenic suppuration. In this conclusion the author differs from Brinton, who studied a smaller number of cases. Pick's analysis shows that the rare ulcers of the fundus are much more likely to rupture into the thorax than those of all other parts of the stomach, but that the occurrence of thoracic complication depends largely on the existence of old adhesions and alterations in the position of the thoracic organs. The exciting cause of the perforation in most cases is mechanical, either by distention from food or gas, vomiting, straining at stool, etc. Death is usually due to complications, rarely to shock. Perforation of the heart does not cause instant death, patients having lived as long as three or four days after hemorrhage began.

The Pathology of Paraplegia in Vertebral Caries, with the Indications for Operation.—According to Dr. Thorburn (*British Medical Journal*), paraplegia may be produced in one or other of the following ways: 1. Mere kyphosis is not usually competent to produce paraplegia. 2. Sudden paraplegia may result in rare instances from fracture of carious vertebræ. The frequency of this occurrence is, according to Kraske, about two per cent. of the total number of paraplegias caused by vertebral caries. 3. Still more infrequent causes are the bursting of an abscess into the spinal canal, hemorrhage into the canal, and displacement of bony sequestra which press upon the cord. 4. The most usual cause of paraplegia is pressure by granulation-tissue. 5. In a few cases true tuberculous periarteritis is found within the cord, generally in association with tuberculous lepto-meningitis. In regard to the prognosis, the author says that his own experience is, that nearly all cases will recover if fixed in the recumbent position for a sufficiently long time, but the time required may be very prolonged. Cases in which the paraplegia is due to intra-medullary tuberculous periarteritis can hardly be expected to get well, and those in which pressure has arisen from fracture of the carious bones are not likely to improve to any great extent. Equally unfavorable are some of the other rare varieties of paraplegia. The following indications for operation are given: 1. A steady increase in symptoms in spite of favorable conditions and treatment. 2. The presence of symptoms which directly threaten life. 3. The persistence of symptoms in spite of complete rest is the indication which has been most commonly adopted. 4. In posterior caries

(caries of the arches) operation is clearly indicated, as here we can readily both treat the paraplegia and remove the whole of the tuberculous tissue. 5. The existence of severe pain if the patient is being exhausted thereby. 6. Children, as a rule, yield better results than do adults.

Contra-indications: The presence of active tuberculous changes in other organs. Macewen holds that we should not operate in the presence of pyrexia. The exception to this would be if the cause of the pyrexia could be removed by operation. General meningitis will probably prove fatal whether an operation be performed or not. Cases of fracture of carious vertebræ are manifestly unsuitable for laminectomy, and most paraplegias of sudden onset will fall into this category.

Idiopathic Rupture of the Heart.—Dr. Collins (*Lancet*) has reported the case of a man, fifty-three years old, who had lived a temperate life, and had been troubled only by dyspepsia and a weak heart. There was no history of rheumatism or rheumatic fever. The man's father had died suddenly of heart disease. After feeling out of sorts for a time, the man experienced severe pain in the precordium and felt too ill to leave his bed. He gradually became worse and sick after food. Speech became thick, the mouth was drawn to the right, and the right eye was partially closed. The left arm became paralyzed, then the right leg. The tongue deviated to the right on protrusion. The sphincters were unaffected. The heart-sounds were faint and without added sounds. The man was moved to a water-bed, his body and head being kept horizontal, and great care being taken to avoid sudden movement. Later, when his pelvis was raised to allow the introduction of a bed-pan, almost instantaneous death ensued. Upon post-mortem examination, prolonged and careful search failed to reveal any microscopic change in the brain, its vessels, or the meninges. On opening the pericardium it was found to be filled with blood-clot, and on washing this away a laceration about one and a half inch in length was found in the left ventricle; the aperture was closed by a recent clot. The cavities of the heart were dilated, the walls thin and in an advanced stage of fatty degeneration. There was no valvular disease. The aorta and its main branches were atheromatous. Both lungs contained calcifying tubercle; the abdomen was loaded with fat; the spleen was soft; the kidneys were engorged, but otherwise healthy.

Confusion between Distended Gall-bladder and Movable Kidney.—Dr. Morris points out that, though on first thought there is not much resemblance between these two affections, the one is often confounded with the other (*British Medical Journal*). The fact that both affections are much more common in women is noted, and the fact that the right kidney is much more movable than the left increases the chances of error. The symptoms common to both are pointed out. Both may present as a tumor in the right hypochondriac and umbilical regions, and the physical characteristics of the tumor from either cause may be similar. The tumor may be movable, and in either case the percussion-note overlying it may be resonant or dull. Both diseases may cause dyspeptic symptoms or give rise to colic. Either may cause jaundice, gastric intestinal catarrh, or even peritonitis. In neither case is the condition of the urine a reliable guide. The conditions of the gall-bladder which tend to render the confusion more probable, are elongation with a reniform outline, mobility, or downward displacement of the liver, with a retroflexed gall-bladder under the viscus, causing the displaced bladder to feel like a loin rather than an abdominal tumor. A tilting of the kidney from behind forward, bringing its anterior end just under the abdominal parietes, or adhesion of the kidney to the right lobe of the liver, might cause the kidney to resemble gall-bladder. To distinguish between the two conditions it must be remembered that a distended gall-bladder, as well as the kidney, is a frequent cause of movable abdominal tumor. The range of motion in the gall-bladder is, however, always in the arc of a circle, the centre of which is a point beneath the right lobe of the liver. The history of a distinct attack of jaundice is an important factor in diagnosis. A distended gall-bladder can generally be felt, whereas a movable kidney often cannot. The gall-bladder, if distended with stones, is much harder than the kidney. Variance in size of the tumors is of no importance, unless with the variance in size there is the history of the passage of large quantities of urine. An attempt should always be made in these cases to pass the hand behind the tumor and palpate the kidney.

The Employment of the Membrane of a Hen's Egg in Grafting.—Dr. Amat gives an account of the case of a young boy whom he had treated for a large burn caused by boiling water in the dorso-lateral region of the right foot. Repair was slow, and the author advised Reverdin's and Thiersch's method of skin grafting, but the family was very much opposed to it. M. Amat then thought it would be well to employ the exceedingly vascular internal layer of the membrane of a hen's egg. He made the attempt and obtained successful results. In 1888 and in 1893, he had the same success in the treatment of burns on the arm, the back, the feet, and the leg. In summing up his observations and those of others, M. Amat found that good results had been obtained in nine cases and failure in seventy-four cases, as regarded the anaplastic value of the membrane of the shell. These favorable results, says the writer, may be attributed to the "action of vicinity" of the graft on the evolution of the embryonic tissue, and not to its nature. There are therapeutic indications for its employment, especially in children, women, and nervous persons. The technique of this operation is as follows: 1. The membrane should be taken from a very fresh egg, as physiological observation has shown that the latent life of this membrane is then more active. 2. Grafting must not be done until the dressings have suppressed the suppuration and provoked a healthy growth. Previously to the transplantation, contact with the air must be avoided by a thick dressing of gauze saturated with a carbolic-acid solution. 3. Take a very fresh egg, break it in the centre, empty it of the contents, and seize the membrane with a mouse-tooth forceps at the large end of the egg—that is, the internal layer of the membrane of the shell. 4. This layer is cut into strips about four or five millimetres in width and of the same length. These are applied on the wound with the point of a pair of scissors, and laid on their albuminous surface. 5. They are applied at a distance of from twelve to fifteen millimetres, and are covered with a small square of tin foil and then by a dressing of gauze saturated with a solution of carbolic acid. This heteroplastic procedure, says the writer, is worthy of attention, especially from practitioners who do not always have at hand the proper material for "inter-human" or "inter-zoo-human" heteroplasty. From this point of view it is interesting to make a trial of this procedure in rural practice.—*New York Medical Journal.*

The Four-years' Course.—Word comes to us that the rapid lengthening of the two years to three and now four courses of lectures as a requirement for graduation is producing hard times in some medical colleges, and will be the cause of a diminution in the number of existing schools of medicine. In some quarters this is a seeming hardship, but, after all, the process is one highly beneficial to the medical profession.—*The Lancet-Clinic.*

New York, August 3, 1895.

A NEW THEORY OF SLEEP.

SINCE the discoveries made by Golgi, Cajal, Retzius, and others of the peculiar anatomical characteristics of the nerve-cells a number of new theories regarding brain-function and brain-action have been in the field. The nerve-cell, as it is now understood, consists of a very large number of long branched processes, which are called the protoplasmic processes, and a single axis cylinder which extends out, becoming eventually the nerve-fibre and giving off fine lateral branches. It has also been shown that each nerve-cell in the brain is in contiguity with some other nerve-cell, or rather with the terminals of the axis-cylinder process of that cell, but that no actual union takes place between the processes from the one cell and fibre process of the other. When one set of nerve-cells, for example, are thrown into activity, impulses are sent out along the axis cylinders and their terminal end-brushes, and these affect by contact the protoplasmic processes of other cells. Cajal and others look upon the axis cylinder and nerve-fibre as conveying impulses out from the nerve-cell or body, while the protoplasmic processes receive impulses brought to them and carry them to the cell-body. These latter, therefore, are sometimes called cellulipetal, while the axis-cylinder process is called cellulifugal. We are speaking, of course, now of the relations of the different groups of cells in different parts of the brain, rather than of the relations of these cells to the spinal cord and parts below. Some time ago Professor Duval proposed the theory of sleep based upon the peculiar relations of the brain-cells and fibres. According to this theory the nerve-cells in repose retracted their processes, which, as he thought, were really pseudopods. The cell processes being thus retracted, the contiguity of the cell with other cells was less perfect, hence their functions became lowered, consciousness was lost, and sleep ensued. Kölliker objected to this view, on the ground that amœboid movements are never observed in nerve-cells, at least of the higher animals; Duval having contended that he had seen such movements in the lower orders of animals. Cajal, siding with Kölliker, states that no matter what way you kill an animal—by shock, strangulation, or anæsthesia—the nerve-cells never differ in aspect, and one never can discover any amœboid movements among them, even when they are placed freshly in the field of the microscope. Cajal has, however, suggested another theory of sleep which he believes more rational and more in accordance with facts. While nerve-cells do not have amœboid movements, there are, scattered richly throughout the brain-tissues, other cells known as neuroglia cells. These are cells with very numerous fine processes, and they form in a large measure the supporting framework of the brain-tissue, sending their fine processes in among the nerve-cells and blood-vessels. Now Cajal's theory is that these neuroglia cells during repose extend or relax their fine hair-like processes. As the result of this the perfect contact between the processes of the nerve-cells and the end-brushes from the axis cylinders that surround them is interfered with, hence the brain function is slowed up and sleep ensues. During activity these neuroglia cells retract their numberless fine processes, the contact between the nerve-cells becomes perfect again, and mental functions are resumed. The practical facts upon which Cajal bases this ingenious theory are that the neuroglia cells are found to be in different states. In some their processes are retracted and shrivelled and in others they are extended. There is unquestionably an amœboid movement, therefore, in this class of cells. Furthermore, it is in accordance, he says, with physiological facts that a cell would retract its processes during activity and relax them during repose. The physical basis of sleep, therefore, according to this view, would be the bristling up of the hair-like processes of the neuroglia cells, a squeezing of them in between the machinery by which the nerve impulses pass, and a sort of a clogging of the psychical mechanism.

Such theories are of course as yet only theories, and may be regarded by practical minds with great contempt. Still, there is sometimes an advantage in scientific hypotheses, even if they furnish only an intellectual exercise to the student.

SURGERY OF THE URETERS AT JOHNS HOPKINS HOSPITAL.

IN a recent issue of the *Bulletin of the Johns Hopkins Hospital* is an interesting account of the brilliant investigation and successful surgery of Dr. Howard A. Kelley, which reflects credit upon the whole American medical profession. It is now several years since Dr. Kelley demonstrated the possibility of catheterization of the ureters, the benefits of which are shown in the diagnosis of obscure kidney trouble, as well as that of a positive differentiation of a diseased kidney from the sound one by the collecting of urine from each separate kidney. He cured a case of gonorrhœal pyelitis and pyo-ureter by irrigation. The treatment of this case, as reported in the *Bulletin*, is most ingenious and satisfactory. In it he demonstrates the following novel and important points:

1. Stricture of the lower extremity of the ureter can be diagnosed without any operation, by using the cystoscope, the bladder being dilated with air by posture.

2. Stricture of the ureter can be improved by gradual dilatation by a series of hollow bougies (catheters) and without a kolpo-ureterotomy.

3. A stricture through which a No. 5 (5 mm. diam.) bougie is passed every day for several weeks will still

hold back the urine if the walls of the ureter above have lost their contractility.

4. Pyo-ureter and hydro-ureter can be diagnosed by drawing off in a few minutes such a quantity of fluid as it is manifestly impossible for the kidney to secrete in that amount of time.

5. Pyo-ureter and pyelitis can be cured by washing out the ureter and pelvis without any preliminary cutting operation to disclose the ureteral orifice (as in the kolpo-uretero-cystotomy of Bozeman).

6. Variations in pressure in the column of fluid in a distended ureter can be demonstrated by a manometer attached to the ureteral catheter.

7. In this way the course of the ureter can be mapped out.

He also reports a very interesting case of uretero-cystotomy, performed several weeks after a vaginal hysterectomy and a sigmoid-proctostomy, making an anastomosis of the lumen of the sigmoid flexure through the lateral wall of the rectum at the pelvic floor without using a suture. There is much daring surgery in these days, much surgical ingenuity, but the question is how large a proportion of it will stand the test of time, or find its justification ten years from now. Yet cases such as these are triumphs of skill in which we can all rejoice.

CHICAGO'S DEPARTMENT OF HEALTH AND THE DOCTORS.

The Doctors' Club, of Chicago, held a meeting on June 28th, at which time the subject of the Board of Health and the Commissionership was brought up. The opinion of all the gentlemen present seemed to be very unanimous and very emphatic to the effect that the Mayor of Chicago had broken his pledges and treated the medical profession with great injustice by his removal of Dr. Reynolds, the former able and successful Health Commissioner. Some very forcible and eloquent speeches were made by a number of members present. The *Chicago Medical Recorder* sums up the situation as follows: "An important medical position has been lost to the profession. The Health Department, so successfully managed by medical men in most European and American cities, has now at its head a ward politician, a place-hunter, who had been dropped by his constituents, and regarding whom no suspicion of ability in or knowledge of sanitary science had been even remotely entertained. The semi-respectable department has been dragged, therefore, in the slime of City Hall politics."

The only voice for the other side was that of Dr. John B. Hamilton, who sided with the Mayor, offering the excuse that, as an official of the Marine Hospital Service, he was obliged to render any sanitary service to the city that the Mayor called for. The Chicago profession seems to have been practically unanimous in urging the reappointment of Dr. Reynolds, and it is naturally extremely indignant over the way in which he has been treated. We trust that the profession of the city will steadily oppose the general acceptance of the idea that doctors cannot possibly be good business men, and therefore should not be appointed to positions calling for business capacity. This extremely absurd position was taken many years ago by the astute politicians of New York, and we have not yet been able to rid our legislators of the delusion.

THE MEDICAL EXAMINERS OF NEW JERSEY.

The fourth annual report of the State Board of Examiners of New Jersey has been published, and shows that the License Board has accomplished a great deal of good work during its brief existence. During this time they have examined 524 candidates and have granted 417 licenses. In other words, about twenty per cent. of those who have applied for a license have failed. The Board has succeeded in repealing the charter of a bogus medical college that flourished for a time in Jersey City. It has secured the passage of a law regulating the practice of midwifery, and this has been in successful operation for two years. It has enforced the registration law, and has secured the passage of a new medical law, which became operative July 4, 1894, and which the Board states is the best State medical law in this country to-day. The law which receives this high praise seems, on the whole, to justify it. It requires that all applicants for license in medicine shall be twenty-one years of age, shall have their moral character well certified to, shall be graduates from a credited college, or have studied at least three years in a high school or academy, and shall have received a diploma conferring the degree of Doctor of Medicine from some legally incorporated medical college, one which is in good standing in the opinion of the Board. The applicant must also have studied medicine four years and taken three courses of lectures. If, however, he has spent one year in a hospital, that counts as a year in the study of medicine.

ANTIVENENE.

The latest application of the serum therapy is in the use of the blood-serum of animals that have been immunized against snake-bites. Dr. Thomas R. Fraser, of Edinburgh, publishes an article in the *British Medical Journal* of June 15th on this subject. Taking the venom of the cobra of India and of the rattlesnake (*crotalus horridus*) of America, he injected these in gradually increasing doses into rabbits, cats, and kittens, until they were able to take injections of ten, twenty, or even fifty times the ordinary lethal doses. Having made certain that these animals were relatively immune against the poison, he took their blood-serum and used it in protective inoculations upon other animals. He established that the blood-serum, or, as he calls it, "antivenene" of animals protected against large lethal doses of venom is able perfectly to prevent lethal doses of the venom of the most poisonous of serpents from producing death. The application of his method to man has not yet been made, but Dr. Fraser looks forward to its being utilized in India, where the annual deaths from snake-bites amount to twenty thousand.

Dr. Behring has received the Cross of an officer of the Legion of Honor of France.

News of the Week.

Proposed International Surgical Congress.—At the German Surgical Congress recently held in Berlin, Professor Gussenbauer announced that a proposal had been received from some American surgeons, that an international surgical congress should be organized, which should meet every five years at different places. The German Congress appeared to be favorably inclined to the proposal.

Dr. William Chapman Jarvis, of this city, died on July 30th at the residence of his brother, Assistant-Surgeon N. S. Jarvis, U. S. A., at Willet's Point, Long Island. Dr. Jarvis was a son of the late Dr. N. S. Jarvis, a surgeon in the army. He was a graduate of the Medical Department of the University of Maryland in 1876, but had always practised his profession in New York. He was Professor of Diseases of the Throat in the University of the City of New York, and was a member of many local societies and a fellow of the American Laryngological Association. Dr. Jarvis was a conscientious student and a careful writer, and had made many notable contributions to laryngological literature; he had also enriched the armamentarium of that branch with several useful instruments of his own invention.

A Substitute for Execution by Electricity.—An Ohio physician proposes that the death penalty be carried out by filling the room in which the condemned man is sleeping with carbonic-acid gas.

Syphilis in Russia.—Syphilis prevails to an excessive degree throughout the Russian empire, over a million patients having been under treatment for this disease in the hospitals of the country during the year 1890. As was shown by Dr. Bulkley in the interesting collection of cases published in his "Syphilis Insontium," this wide prevalence of syphilis in Russia is not due so much to unusual licentiousness as to the careless and uncleanly habits of the people. A soldier returning to his home with syphilis contracted during his service in the army, will often infect his own family, and even the entire village, through the common use of table utensils, towels, and pipes. The necessity of energetic measures to prevent the further spread of this disease has so impressed itself upon the Russian authorities, that the subject will be given an important place among the discussions at the International Congress, which will meet at Moscow next summer.

An International Language Society.—A correspondent of a London contemporary suggests that those who desire to see the general use of some one language for contributions to medical literature would probably advance their object in a practical way by forming themselves into an international society, somewhat upon the model of the New Sydenham Society, the object of which shall be the publication of translations of important medical papers and monographs in the selected language. It would be somewhat in the nature of putting the cart before the horse to found a society for the propagation of a language before deciding upon the language.

"Talks with the Doctor."—Under this title, one of the daily papers gives daily counsel to the individuals who apply for prescriptions. One correspondent asks directions for taking bromide for a nervous headache, and is told to take from fifteen to thirty grains every two or three hours. The advice to take as much as thirty grains of bromide every three hours without any further qualifications is certainly dangerous, and the prescription is another illustration of how impossible it is to prescribe safely and effectively through the columns of a daily paper. "Counter-prescribing" by druggists, we think, on the whole, would be a little safer.

Dr. Max Simon Nordau, the eminent degenerate, is about to follow the example of some others of his class and enter general literature. He is reported to be now at work on a novel, and to have given out that when that is finished he will write a play. He has been earning money with his pen, we are told, since he was fourteen years of age, and he is still on the bright side of fifty.

Cholera in Japan.—Notwithstanding recent semi-official denials, cholera appears to be more than usually prevalent in Japan this summer. Advices from Tokio, of July 12th, say that there is every premonition of a serious epidemic. The disease has appeared among the troops at Pescadores, Port Arthur, and Chin Chow, its germs having been carried by returning soldiers. There are fourteen centres of infection from which reports of fresh cases reach the authorities daily. The government is making strenuous efforts to check the epidemic. Since the outbreak of the disease up to the end of July, there were 9,000 cases of the disease and 5,000 deaths. The cholera is raging also in several cities of Corea.

Assault on a Physician.—Dr. George Drury, of Brooklyn, was called by telephone last Saturday to visit a person said to be at the point of death. He went to the place indicated, a house that had been for some time unoccupied, and was conducted by a man who opened the door to the upper floor. Here he was set upon by his conductor and another man, beaten and gagged, and robbed of his money, watch, and jewelry. The watch and jewelry have been recovered in a pawn-shop in this city, and the authorities hope to apprehend the criminals. Another Brooklyn physician was called recently by telephone on an errand similar to that which led Dr. Drury into the trap. When he arrived at the house a woman answered the bell and said that no one was sick there. Just as he was about to leave, a man came to the door and said that the sick person was upstairs. The doctor's suspicions were aroused, however, and he refused to go inside.

The Water-Supply of London is at the mercy of private companies that are unable to furnish all the water needed and that are allowed to charge full price to the consumers whether they give a constant supply or not. At present the meagre supply of water in the eastern part of London is causing increased suffering to the inhabitants of that section. The streets are filled with women offering threepence or more for a bucket of

water, but they are unable to get it even at that price, for the very good reason that there is none. The death-rate in East London has been doubled since the companies began turning off the flow of water except for about two hours in the twenty-four.

An International Congress of Applied Chemistry will be held in Paris next year. A preliminary programme of the sections has been drawn up for consideration. They are to be ten in number, and will cover the entire field of industrial chemistry.

Testimonial to Sir Joseph Lister.—Sir Joseph Lister was presented on July 30th with his portrait, painted by Mr. J. H. Lorimer. The presentation was made at a meeting held at King's College Hospital by Sir John E. Erichsen, President of University College.

Yellow Fever in Havana.—The medical inspector of the United States Marine Hospital Service at Havana states that in the week ended July 25th there were seventy new cases of yellow fever in that city and twenty-three deaths.

Dr. George B. Fowler has been appointed by Governor Morton to the State Board of Health as the Commissioner representing the city of New York.

The Grand Duke George, Tsarewitch of Russia, is suffering from pulmonary tuberculosis in an advanced stage. He proposes to spend the coming winter in Algiers.

The School of Medicine for Women in St. Petersburg is now, thanks to private liberality, on a firm foundation financially and will soon be ready for work. The curriculum, which is to extend over five years, will be the same as that of the medical faculty in the university, and will be open to single women over twenty-one years of age. Single women of younger age and married women must be supplied with a written permission from their parents and husbands respectively. All students must know a certain amount of Greek and Latin. A clause provides that a woman holding the school's diploma will not be eligible as director of a general hospital.

The Proportion of Multiple Births.—In a paper read before the New York State Medical Society some years ago Dr. James V. Kendall reported 875 cases of childbirth occurring in his own practice, among which were 17 cases of twins, or 1.71 per cent. This is much higher than the average, as stated by Dr. Drejer, which we noted recently as being 1.17 per cent.

The British Medical Association, which met this week, promised to be one of considerable interest in the matter of ethical debates. Among other questions proposed for discussion were "Intra-professional Etiquette," "Advertising," "Unqualified Assistants," "Gratuitous and Cheap Contract Practice," and "Hospitals and Dispensaries." Mr. Lawson Tait promised to introduce another cause for acrimonious dispute in the shape of a resolution denouncing the proposed Midwives' Registration Bill.

The Attractiveness of New York.—The editor of an esteemed St. Louis contemporary apologizes to his readers for a delay in the issue of the journal, alleging the wholly valid excuse that he was detained in New York. Another esteemed contemporary, the *Medical and Surgical Reporter*, after existing for forty-two years in Philadelphia, has come to live in New York amid congenial surroundings, where medical thought is active. We welcome the *Reporter* to the medical centre and wish it many years and a constantly increasing circle of readers.

The Memory of the Late Dr. Dujardin-Beaumetz has recently been honored by the erection of a bust in the garden of the Hôpital Cochin, in Paris.

Obituary Notes.—Dr. Walter A. Morton died at his home in Brooklyn on July 22d. He was thirty-six years of age, and was a graduate of the Dartmouth Medical School in 1890.—Dr. Benjamin S. Mackie, aged fifty, a surgeon in the United States Navy, with the relative rank of Lieutenant-Commander, was found dead on July 25th in the library of his residence, in Philadelphia, with a bullet-hole through his head. He had committed suicide. Dr. Mackie entered the navy in 1869. His last service was aboard the cruiser Chicago. He had been on waiting orders for several months.—Dr. Richard Reasoner, of Morrisonville, Ill., was shot and killed, on July 24th, by a man whose wife had been under his professional care. The woman had become insane, and her husband believed it was in consequence of the doctor's treatment, and had threatened several times to take his life.

Texas Fever in the Southern States.—A telegram from Louisville states that a proclamation has been issued by the Kentucky State Board of Health quarantining against cattle from Virginia, North and South Carolina, Mississippi, Indian Territory, Alabama, Texas, Louisiana, Arkansas, Georgia, and Florida, giving as a reason for this action that Texas fever has been introduced into these States recently and a number of cattle have died of it. The quarantine is to be maintained during all the year except December, January, and February.

Cholera and Quarantine.—The English journals have taken very much to heart the charge made by M. Henri Monod, at a meeting of the Comité Consultatif d'Hygiène of France, that England is to blame, by her refusal to ratify the Paris Convention, for the occurrence of cholera this year in Mecca. They, of course, repel the charge, but seem to be rather hard pushed at times to do so convincingly. *The Lancet* says that M. Monod should remember that if France would only give up her quarantine notions in the Red Sea, the way of England to do that which is right would be much clearer. "It is quarantine in the Red Sea that endangers the lives of Indian pilgrims and constitutes the main, if not the sole, danger of cholera reaching Mecca by way of the sea. If our pilgrims were only allowed, when certified after a long voyage to be free from cholera, to sail on to Jeddah the danger of cholera travelling by the sea route would practically be at an end." We have often seen it stated in the interests of commerce that quarantine was ineffectual as a means of staying the advance of cholera and other pestilences, but that effective quarantine not only fails to stay the progress but even favors the advance of epidemic disease is a rather strong assertion.

Society Reports.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 13, 1895.

GEORGE P. BIGGS, M.D., PRESIDENT, IN THE CHAIR.

Aneurism of the Arch of the Aorta was presented by DR. E. HODENPYL. The aneurism was so large that it caused extreme pain, and the patient, a German, thirty years of age, killed himself to be rid of the pain. He had complained for a considerable time of pains in the chest. He committed suicide by shooting himself twice in the left breast. Both bullets pierced the pleural cavity, but did not injure the lung. He was perfectly conscious for some hours after the shooting. At the autopsy, besides the conditions brought about by the shooting, there were extensive hemorrhages into the pleural and abdominal cavities; the heart lay high in the chest, and immediately below it was a large mass which was close to the vertebral column, and pressed toward the median line by a large quantity of blood in the pleural cavity. This mass was removed in conjunction with the heart, and then it was found that the mass occupied the lower lobe of the lung on the left side, and was very hard. An aneurism was found at the beginning of the arch of the aorta, and at the beginning of the thoracic aorta was a large, sacculated aneurism containing a considerable amount of laminated fibrin. The aneurism had pressed posteriorly, but chiefly laterally, and had replaced almost completely the lower lobe of the lung. Some of the vertebræ had been eroded.

Abscess of the Liver.—Dr. Hodenpyl then presented two specimens of the above. The first specimen was removed from a man, fifty-two years of age, who had suffered from irregular chills and fever for five or six weeks previous to his admission to the hospital. He was in a semi-comatose condition at the time of admission, and all that could be gathered from his statements was that he had had a cough with muco-purulent expectoration for two weeks, and also pain in the epigastrium and right hypochondrium. There was no history of his having had diarrhœa at any time. His temperature was normal, the pulse 130 and weak. A needle was inserted in the eighth interspace posteriorly in two places, but only dark blood was withdrawn. There was tenderness over the region of the liver, and slight dulness over an area about three inches in diameter. The aspirating needle was also inserted in the median line, but no pus was obtained. At the autopsy the liver was found to have been converted into a series of inter-communicating cavities. No amœbæ were found.

The second specimen was removed from a man, twenty-five years of age, who had had irregular attacks of dysentery at frequent intervals ever since early childhood. For the last two months the dysentery had been uncontrollable, there having been daily upward of twenty movements containing blood and mucus. There had been no elevation of temperature during his stay in the hospital. At the autopsy a well-marked ulcerative colitis was found, and an enormous abscess of the right lobe of the liver. There was a marked compensatory hypertrophy of the left lobe of the liver.

Hypertrophy of the Prostate and Castration.—Dr. Hodenpyl then exhibited two specimens of hypertrophy of the prostate. One of them showed the effect of castration. The first specimen had been removed from an old man who had suffered intensely from obstruction of the bladder, due to an enormous hypertrophy of the prostate. Castration was performed, and this resulted in a shrinkage of the prostate, and a restoration of the power of voluntary urination. Perforation of the bladder had occurred behind and a little above the prostate, and as a result, a general suppurative peritonitis. The second specimen showed an enormous prostate gland. It had been removed from the body of a man, sixty-two years of age, who had died of some intercurrent disease. There had not been any marked difficulty in urination. In the fresh state the prostate measured four inches across as the bladder was opened. The bladder was capable of containing only between one and two ounces of urine.

DR. J. W. BRANNAN said that the patient from whom the first specimen of abscess of the liver had been removed, had been under his care at the St. Francis's Hospital for about a week. The chief symptoms had been pain in the region of the liver, and moderate tenderness. There had been an enlargement of the liver, so that it could be mapped out by percussion for two and a half inches below the costal margin, and there had been dulness posteriorly up to about the eighth rib. There had also been very marked diarrhœa. The exploratory punctures had been made chiefly with reference to the lung, but one puncture had been made with a view of determining the existence of any collection of fluid in the liver. Nothing but dark blood had been obtained. The case had taught him the advisability of repeating the punctures if at first no pus were obtained. Judging from his experience in one case of amœbic dysentery, he would have expected to find the amœbæ in the intestines chiefly; hence, it was unfortunate that no examination of the intestines had been made.

The case of abscess of the liver reported by Dr. Edebohls, in which relief had been repeatedly given by operation, had also been under his care, and he had studied it very carefully. It was a case of amœbic dysentery. At the first operation, the liver had only been attached to the abdominal wall, but after firm adhesions had formed, the liver had been punctured and drained.

The autopsy in that case had shown a complete absorption of the adhesions that had formed at the first operation between the capsule of the liver and the abdominal wall. The liver was of normal size, and yet a large part of the liver tissue had been destroyed. Microscopical examination had shown extensive dilatation of the blood-vessels with cirrhosis of the liver, and also that there had been an extensive reproduction of the liver tissue.

Cardiac Hypertrophy, Endocarditis of Mitral Valve, and Free Chordæ Tendinæ.—DR. F. FERGUSON presented specimens from a case of the above. They had been removed from a man, forty-four years of age, who had been admitted to the hospital service of Dr. W. G. Thompson, on September 20, 1894. There was no family history bearing on his condition; his habits were regular, and there was no history of rheumatism. Some six months prior to his admission, he caught cold, and since that time he had complained of dyspnœa. He had suffered recently from constipation and hæmorrhoids. He had been unable to sleep on account of pain over the liver and region of the heart. On admission his abdomen was swollen, and he complained chiefly of shortness of breath. His temperature was 97.8° F.; respirations, 32; and pulse, 108. On physical examination, there were signs of consolidation and of fluid at the base of the left lung. The cardiac apex was at the sixth intercostal space, four and a half inches to the left of the median line. There was a loud, blowing, systolic murmur over the cardiac area, with point of intensity over the apex, and heard distinctly over the left chest posteriorly. This murmur obscured the first sound of the heart. The cardiac action was slow, regular, and of fair force, but the pulse was irregular and intermittent. There was distention of the veins of the neck. The area of liver dulness was normal; splenic area was not determined. The abdomen was distended

and tympanitic over the central area, but dull along the flanks; and on percussion there was the characteristic fluid wave. The tongue was deep red, and slightly fissured. He was slightly anæmic, but fairly well nourished, and his general condition appeared fair; but there was well-marked œdema at the ankles and on the legs. His dyspnœa became aggravated, and on October 1st his right pleural cavity was aspirated and sixty-four ounces of clear serum withdrawn. During the month of October he was troubled with incessant cough, insomnia, and restlessness, and was at times delirious. His urine was alkaline. It had a specific gravity of 1.020, and contained varying quantities of albumin, from a trace at the date of his admission to twenty-five per cent. by volume on November 1st. He also suffered from coldness of his extremities, and the face was cyanotic. All his symptoms varied from time to time—now fairly rational, and again, delirious; but there was a general and progressive decline, and he died on November 23, 1894. There was only a trace of albumin in his urine at the time of his death. His treatment had consisted in the use of fluid diet, tonics, stimulants, and diuretics.

At the autopsy there was found emaciation of the body, but no œdema. There was marked anæmia. The peritoneal cavity contained 500 c.c. of straw-colored serum. In the right pleural cavity were 800 c.c. of blood-stained serum, but the left pleural cavity contained no fluid. The pericardium was normal. The heart was large, weighing seventeen and a half ounces. Its cavities were moderately dilated; the wall of the left ventricle was moderately hypertrophied, and that of the right ventricle considerably thickened. The muscular tissue was of a dark-red color. The aortic, tricuspid, and pulmonary valves were normal. The mitral valve was slightly reduced in capacity, with thickening of the anterior segment. Five of the chordæ tendinæ were free, being detached close to their fleshy columns, without any evidence of their previous attachment on the surface of the endocardium. All the organs gave evidence of prolonged hyperæmia. The bladder was enormously distended, containing 700 c.c. of cloudy urine. Its walls were thickened. There was a diverticulum of the posterior wall, with an estimated capacity of 30 c.c. This communicated with the bladder by an opening 1 ctm. in diameter. The prostate was enlarged, especially the right lobe, which encroached upon the urethra, and must have caused considerable obstruction to the outflow of urine.

Mitral and Aortic Stenosis.—Dr. Ferguson also presented another heart. It had been removed from a man, thirty-one years of age, a glass-worker by occupation. He had been admitted to the service of Dr. W. H. Draper at the New York Hospital on January 28, 1895, suffering from dyspnœa. He stated that he had had several attacks of heart failure, and had been subject to cardiac disease for years. He died shortly after his admission to the hospital. At the autopsy, inspection showed the body to be well nourished, and free from œdema. There were 300 c.c. of blood-stained serum in the right pleural cavity. The same quantity of similar fluid was found in the left pleural cavity. The heart was slightly increased in size, the wall of the right ventricle being enormously hypertrophied, and the ventricle moderately dilated. The valves in the right ventricle were normal. The left ventricle was slightly dilated, but its wall was normal in thickness. Two of the aortic cusps were blended together over a distance of 1 ctm., and all the cusps were thickened and retracted. There was thickening and retraction of the segments of the mitral valve. It admitted a probe only 1 ctm. in diameter. There was great dilatation of the left auricle, with thickening of its wall. There were intense congestion and œdema of the lungs. The liver was nutmeg in appearance. All the other organs presented the appearances associated with prolonged passive hyperæmia.

Epithelioma of the Œsophagus.—Dr. Ferguson presented still another specimen. It had been taken from a man, forty-four years of age, who had been admitted to the service of Dr. Frank P. Murray on January 17, 1895. During last July, while employed in beating carpets, he experienced considerable trouble with his throat. Two months later, he noticed difficulty in deglutition, and regurgitation of food through the nasal passages. During the three months prior to his admission he had not been able to swallow solid food. Since the beginning of his sickness, his voice during wet weather had had a nasal quality. He had recently suffered greatly from dyspnœa and dysphagia, and had lost flesh and strength. There was no family history bearing on his case, and he had always enjoyed good health up to the commencement of his present illness. On examination, a tumor was found in the larynx, principally on the left side. It was firm and nodular, and adherent, but not tender on pressure. There were enlarged cervical glands. The cachexia was marked. Owing to his extreme dyspnœa, he was submitted to tracheotomy, from which he reacted favorably, and with a considerable improvement in respiration. The operation was performed on January 19th. Four days later, there was distinct redness and swelling on the left side of the wound, and this was followed by greater difficulty in deglutition. Three days after this, there was a fluctuating area to the left of the tracheotomy wound, which, when incised, gave vent to a half-drachm of pus. Since the latter part of January, he had been fed by nutritive enemata, being unable to take any nourishment by the mouth. He rapidly declined, there being slight fever, but no pain. He died on February 6th. The autopsy showed a lobulated tumor, which completely filled the upper part of the œsophagus and lower part of the pharynx. It measured 13 ctm. vertically, and 4 ctm. antero-posteriorly. Its greatest transverse measurement was 5 ctm. It projected into the rima glottis and the space behind the epiglottis, apparently completely filling them. The left arytenoepiglottidean fold was displaced inward by the pressure produced by the development of the tumor. The base of attachment was the posterior wall of the pharynx, and the posterior and lateral wall of the œsophagus, down to the lower border of the cricoid cartilage. Below this level it extended downward, and was attached to the anterior wall of the œsophagus. The entire area of attachment was 10 ctm. in the vertical direction, and about 7 ctm. laterally. There was a very narrow opening along the right side of the œsophagus, through which a small probe could be passed. There was also a narrow, irregular channel in the interior of the tumor. The œsophagus was normal below the tumor. The posterior wall of the trachea, just below the larynx for a distance of 5 ctm., bulged forward from the encroachment of the tumor. The tracheotomy opening was situated in the median line, 10 ctm. above the bifurcation, and just below the bulging of the tracheal wall already mentioned. There was extreme emaciation of the body. An old tubercular lesion was found in both apices, but chiefly in the right lung. There was also a small tubercular nodule in the liver. There was chronic diffuse nephritis. Microscopical examination showed the structure of the tumor to be that of an epithelioma. On the surface it presented in places the appearances common in ordinary papillomata.

The President said he was extremely interested in the specimen showing free chordæ tendinæ. Their free ends were perfectly round, club-shaped, and fibrous, and there was not the slightest appearance of a recent endocarditis. It was rather hard to explain how they had become free. The question arose here as to whether, with a simple rheumatic endocarditis, there might not be a weakening and rupture of some of the chordæ tendinæ. The murmur in this case was said to have been unusually loud and widely diffused, and en-

tirely different in character from other cardiac murmurs. Although careful search was made, no points had been discovered to indicate where the chordæ tendinæ had been attached.

Dr. J. W. Brannan said that it was usually stated in the text-books that if one were in doubt as to whether an apex murmur was due to stenosis or regurgitation, the size of the heart would decide the matter; in other words, if the left ventricle were small and the disease had existed some time, the existence of stenosis was pretty certain, whereas if there were regurgitation present there would also be hypertrophy. He would like to know whether pathological studies confirmed this statement.

Dr. Ferguson replied that the left ventricle would be abnormally small, commensurate with the stenosis. This would be so even if moderate regurgitation were present, the wall becoming thin and the cavity reduced in size.

Dr. Brannan said he had found it difficult to believe that the statement to which he had just referred was strictly correct, because after the enlargement of the right side of the heart, it would seem as if in time the left ventricle would also become at least dilated in order to keep up the circulation.

Dr. H. P. Loomis called attention to the fact that in the specimen presented the adherence of the cusps must have interfered with the circulation in the coronary arteries.

The President said, regarding the point raised by Dr. Brannan, that as pure and simple mitral stenosis rarely occurred, the value of such a method of clinical differentiation was not very great.

Primary Cancer of the Lung.—Dr. H. P. Loomis presented the specimen. It had been removed from a man sixty years of age. It was situated at the lower and posterior border of the lower lobe of the left lung, and measured in its vertical diameter two inches, antero-posteriorly one and three-fourths inches, and laterally two inches. It was irregular in shape, and distinctly lobulated. The lobules were more or less completely surrounded by a fibrous capsule. The tumor was firm, and of an opaque, whitish-yellow color. A large branch of the pulmonary artery, which was still open, ran through the centre of the mass from above downward. The pulmonary tissue surrounding the tumor presented the characteristic appearances of white pneumonia. The bronchial tubes throughout the consolidated portion showed the evidences of a bronchitis. The lung over the tumor was firmly adherent to the chest wall, and a slight quantity of serous fluid was found at the bottom of the left pleural cavity. The right lung was perfectly normal, with the exception of hypostatic congestion of the lower lobe, and some old pleuritic adhesions. The kidneys presented the characteristic appearances of a chronic diffuse parenchymatous nephritis. The heart was hypertrophied, and the aorta showed the evidences of extensive atheromatous changes. With these exceptions, all the other organs were normal. A most thorough and complete examination was made of every organ and tissue of the body to ascertain if there were any evidences of cancerous development in other parts. This examination included the mouth, larynx, œsophagus, digestive tract, bladder, mediastinal tissues, brain, and the bronchial and retro-peritoneal glands. No abnormal growth was found anywhere except in the left lung. Microscopical examination of sections taken from different portions of the neoplasm showed it to be a medullary cancer (carcinoma molle). The new-growth seemed to spring from the epithelium of the mucous membrane of the bronchi. In some places an apparently pre-existing alveolar structure, as if the cancer-cells had filled the air-cells, could be made out. No pulmonary lesion was diagnosed during life. The man had been an inmate of the almshouse on Blackwell's Island for a long time, and had died, as far as could be ascertained, rather suddenly.

Primary cancer of the lungs, the speaker said, was one of the rarest pathological lesions found. In twenty-seven cases obtained from the literature of this country and Europe, and analyzed by Reinhard, only one lung was involved in nearly all of the cases, eighteen times in the right, and nine times in the left lung.

Aneurism of the Aorta with Multiple Thrombi was presented by Dr. George P. Biggs. The specimens had been removed from a woman, thirty-four years of age, who had complained of dyspnœa and slight œdema of the lower extremities for a number of months. Shortly before admission the dyspnœa increased, and was associated with cardiac palpitation and dimness of vision. The temperature was 102.2° F.; the respirations, 28; and the pulse, 96. Physical examination showed only congestion of both lungs posteriorly. The cardiac area was considerably enlarged, and the apex beat was in the sixth space, four inches to the left of the median line. There was a blowing systolic murmur, and the action of the heart was tumultuous. The abdomen was large, and appeared to contain some fluid. The urine had a specific gravity of 1.024, and contained five per cent. of albumin. Dyspnœa was the chief symptom. The temperature remained elevated, the pulse became more feeble, and she died on the fourth day after admission. At the autopsy, the adipose tissue of the abdominal wall was found to be 5 ctm. in thickness. There was slight general œdema. The peritoneum contained 400 c.c. of very bloody fluid. The small intestines presented a number of dark, reddish-brown areas, the color extending into the neighboring mesentery for a short distance, and involving portions of the omentum, and in one place the transverse colon. These dark-red areas were covered with a thin layer of fibrin, and the intestinal wall was soft and easily torn on manipulation. In the right pleural cavity were 200 c.c. of bloody fluid. The left pleural cavity was obliterated by old adhesions. The heart was greatly enlarged, weighing twenty-two ounces. The cavities were generally hypertrophied and dilated. The muscular substance was soft, flabby, and mottled in appearance, due to extravasations of blood. The valves of the right side were all normal. The aortic cusps were slightly thickened and retracted. The interesting feature was an aneurism, beginning unusually low down in the aorta—*i.e.*, at its very beginning—and involving the anterior wall, and pressing forward against the pulmonary artery. The aneurism measured 4½ ctm. vertically, 5 ctm. transversely, and about 1½ ctm. in depth. The left coronary artery arose from the aneurism itself. The left lung was poorly aërated, congested, and slightly œdematous; the right lung was similarly congested, but contained three hemorrhagic infarctions, two in the lower lobe, and one in the upper lobe, the largest being in the base and measuring 5 ctm. in diameter. In the vessels leading to these infarctions were very firm antemortem thrombi, adherent to the vessel wall. The spleen was moderately large and soft, and in it were a number of reddish areas, very suggestive of obstructed circulation, but they were not infarctions. The kidneys were quite large, and showed evidence of parenchymatous and slight interstitial change. The liver showed chronic congestion. Along the greater curvature of the stomach a number of small vessels in the submucous coat were very prominent, owing to thrombi in them. In the intestines the fecal matter was abundant and very bloody. The reddish-brown areas of peritoneum showed on examination that the wall was hemorrhagic throughout, and the mesenteric veins from these parts were the seat of multiple thrombi. The arteries were perfectly free. No thrombi were found in the other vessels.

A Peculiar Ulcer of the Duodenum.—Dr. Biggs also presented a specimen which had been taken from a sailor, forty-five years of age, who had entered the Hudson Street Hospital complaining of abdominal

pain which had existed for two or three days. The pain had begun in the umbilical and epigastric regions, so that at first he had been supposed to have appendicitis. Under this supposition an operation was performed, and the appendix found inflamed upon its surface, as was also the entire surface of the peritoneum. Nothing was found in the appendix. The man died on the second day after the operation. No cause had been found for the peritonitis. The autopsy showed the stump of the appendix in good condition, with adhesions formed over it. The peritonitis was quite intense. Further search showed the lower end of the duodenum to be dark and almost gangrenous. On its superior wall was a very peculiar destruction of tissue. The mucous membrane was destroyed over a triangular area, about one centimetre across. The edges were sharply defined, and the base of the ulcer was formed of sloughy tissue, deeply stained with bile. Between the pancreas and the ulcer the tissues were found to be extensively infiltrated with pus, and the peritoneum in this neighborhood was thickly covered with fibrin. The site of the ulcer was really at the extra-peritoneal portion of the duodenum, but the inflammation had extended to the peritoneum, and caused the general peritonitis. Duodenal ulcers were generally in the first portion of the duodenum, and were like the round, punched-out ulcers found in the stomach. It had been suggested that the slough might have been due to a thrombosis of the veins, but no such condition could be found.

Dr. Hodenpyl said that about three years ago he had presented to the Society an aneurism in the same situation and of about the same size, but in his case there had been an opening into the pulmonary artery.

The Society then went into executive session.

Stated Meeting, February 27, 1895.

George P. Biggs, M.D., President, in the Chair.

Multiple Aneurisms of the Abdominal Aorta and Iliac Arteries, with Old and Recent Ruptures, and Absence of Left Common Iliac.—Dr. T. Mitchell Prudden presented specimens from the above. He was indebted for the specimens to Dr. Clement Cleveland, in whose care the patient had been. The patient, a man of middle age, died after an acute illness with symptoms of hemorrhage into or behind the abdominal cavity. The body was well formed and nourished, and at the autopsy about half a litre of bloody fluid was found in the abdominal cavity. The diaphragm was pressed upward. The heart was pale, and with the exception of a slight fatty degeneration of the aorta above the valves, and a very slight thickening of the edges of the mitral valve, the heart was normal. In the left lung there was evidence of slight bronchitis. In the upper and lower lobes of the right lung there was limited œdema. In both lungs there was considerable emphysema at the edges. The spleen was slightly enlarged and soft. The liver was normal in size, but pale and flabby. The pancreas was normal. The right kidney was pale, and contained several small cysts; otherwise in the gross examination the kidneys were apparently normal. On removing the intestines, which were pushed strongly forward, a large, dark-red, ovoidal mass, about twenty-five centimetres long and fifteen centimetres thick, was found bulging forward on either side of the spinal column. This was clotted blood infiltrating the post-peritoneal fat and connective tissue. Blood, fluid and clotted, was found to have densely infiltrated the mesentery nearly to its intestinal border, the lesser omentum, and the entire extra-peritoneal connective tissue posteriorly and laterally. The aorta was normal down to a point about four centimetres below the origin of the renal arteries. Here the lumen was slightly narrowed by a thin projecting portion of its wall. Between this point and the point of bifurcation, the aorta was distended in the form of an ovoidal aneurism, 9 ctm. long and 6 ctm. in its widest diameter. The right common iliac artery opened from this aortic aneurism with its normal diameter, but immediately widened to a cylindrical sac, about four centimetres in diameter. At the lower end of this sac the external and internal iliacs passed off with about their normal dimensions. The left common iliac artery was absent, the external and internal iliacs arising together from the lower end of the aortic aneurism. The left external iliac maintained for about two centimetres from its origin its normal diameter, then widened into a fusiform dilatation, about four centimetres long and 2.5 ctm. wide at the middle. The left external iliac had its normal diameter for about one centimetre from its origin in the aorta. Here it presented an abrupt anterior aneurismal pouch, about five centimetres long and four centimetres wide. Below this the vessel maintained a diameter of about 2.5 ctm., varying somewhat on account of shallow, irregular sacculations. From the lower end of this dilated vessel, its anterior and posterior branches arose with normal diameters. The entire wall of the lower portion of the aorta and the iliacs, from the upper end of the abdominal aneurism as far down as the level of the origin of the internal iliac branches, was the seat of chronic arteritis and endarteritis. The walls were thinned in places, in others thickened and roughened. They were the seat of fatty degeneration and atheroma, and in a few spots were calcified. Old and dense, and closely adherent parietal clots, were present in various places. The most voluminous of these was in the cylindrical dilatation of the right common iliac, and in the sacculated enlargement of the left internal iliac. On the inner side of the dilated, right common iliac, was an old depressed scar, about four centimetres long, and at this point the inner layers of the vessel had ruptured at some earlier period, and had drawn apart at the middle to a distance of about seven centimetres. This earlier rupture had healed by the formation of a dense layer of fibrous tissue in connection with the adventitia. On the left side of the aortic aneurism, and running obliquely upward and forward, was a fresh, gaping complete rupture of the wall of the aneurism, about seven centimetres long, through which the blood had found its way into the surrounding tissue.

The special points of interest in this case were: 1, the malformation of the iliac; 2, the multiple aneurisms in a limited region; 3, the extensive interstitial, post-peritoneal hemorrhage from the ruptured vessel; and 4, the marks of an extensive earlier rupture of the iliac, which had spontaneously healed.

An Enormous Goitre in a White Mouse was presented by Dr. E. Hodenpyl. The mouse had been obtained from a dealer in these animals. The growth was about one-fourth the size of the mouse. A section of the growth was exhibited under the microscope, and this showed it to be a typical goitre.

Stricture of the Œsophagus with Epithelioma.—Dr. Hodenpyl then presented a specimen of the above. The stricture had been almost complete, and the course of the disease unusually rapid, being less than three months. The specimen had been removed from a man, about forty-five years of age, who had complained about three months before death of beginning dysphagia. This increased until at the time of his admission to the hospital he was unable to swallow either liquids or solids. He died of exhaustion. The epithelioma was found about eleven inches from the teeth. There were no other complicating lesions in the body.

Multiple New-growths of the Lung, Mediastinal, and Mesenteric Glands, Liver, and Stomach.—Dr. Hodenpyl also presented the specimens. They had been taken from a man, forty-three years of age, a fireman by occupation. While on active duty in the Fire Department of New York City last May, he slipped, and while

prostrate, was struck on the left shoulder with some heavy body. He soon began to suffer from lancinating pains in the left chest. Shortly after the accident he expectorated a little blood. A physician who examined him at the time of the accident, said that no bones had been broken. Last July, quite a large amount of bloody fluid was withdrawn from the left chest. At the German Hospital, he was subsequently aspirated five times, and bloody fluid withdrawn each time. Last December, he entered St. Francis Hospital. At this time his temperature was 98.4°, the pulse 120, weak and intermittent, and the respirations 22, costal and labored, and the movement of the left side of the chest was slower. Physical examination showed dulness on percussion over the left side anteriorly, from the clavicle to the margins of the ribs, extending to the right edge of the sternum and into the axilla. Posteriorly on the left side there was absolute dulness from the supra-spinous fossa down over the scapula, and from the lower angle of the scapula to the base there was absolute flatness. In the inter-scapular region were exaggerated vocal resonance and fremitus. At the base of the left lung there was an almost entire absence of resonance and fremitus. The heart sounds were weak, and the apex beat was very indistinct. The patient was aspirated, and about one quart of blood-stained serum obtained. The dyspnœa was not at all relieved by the aspiration; the pulse became weak and very irregular, and he complained of a sense of oppression in the chest. There were also dysphagia, choking, and regurgitation of fluids. After a few days the left arm became swollen and very painful, and pitted deeply on pressure. Along with this there was some swelling of the abdomen and scrotum, and signs of fluid in the abdominal cavity. He gradually became weaker and drowsy, and for a few days before death was semi-comatose. He died on January 18, 1895.

At the autopsy, a considerable quantity of slightly bloody fluid was found in the abdominal cavity, but there was no evidence of peritonitis. The pericardial sac contained about one quart of bloody fluid. The left pleural cavity was distended with clear serum. There were no adhesions over the right lung, which was emphysematous. There was fresh fibrin on the pericardium. The left lung had been nearly converted into a mass of new-growth, and the mediastinal glands were enormously enlarged, causing great compression of the trachea and œsophagus. At the root of the neck, just above the heart, was a large mass, about two pounds in weight, which also encircled the large vessels at the neck. One of the ribs showed a healed fracture with much callus. The liver was large, and contained many nodules of new-growth. The spleen was enlarged and soft. Around the cardiac orifice of the stomach were numerous enlarged glands containing new-growth. The stomach was contracted, and in its wall was a deeply ulcerated nodule the size of a walnut. This nodule projected directly into the cavity of the stomach. At the beginning of the duodenum was a marked contraction of the lumen of the gut. The bladder was normal. The heart was carefully examined for an old rupture, but none was found.

Sections of the growths were exhibited under the microscope. That from the lung seemed to be a typical carcinoma. It had a well-marked alveolar structure, the alveoli being filled up apparently with epithelial cells. The speaker said he had not been able to discover connective tissue between these cells. On the other hand, in the liver and the involved mesenteric lymph nodes the alveolar structure was still preserved, but the cells were quite spindle-shaped, and here and there there was apparently a little fibrilla of connective tissue between the cells. He was therefore still in some doubt as to whether this was a case of primary carcinoma of the lung, or a sarcoma of the mediastinal glands, with secondary involvement of the lung, liver, and mesenteric glands. So far as could be ascertained, the man had been in perfect health up to the time of receiving the injury. This gave the case unusual interest.

Dr. Prudden said that, from the description given by Dr. Hodenpyl, it would seem proper to make a diagnosis of both carcinoma and sarcoma.

Dr. F. Ferguson asked if it were common to see sarcoma of the liver so generalized. He would not lay much stress upon the size and shape of the cells in such a rapidly growing tumor.

Dr. Hodenpyl replied that he did not wish to be understood as saying that he laid great stress on the shape of the cells.

Congenital Absence of the Right Kidney; Displacement of the Left Kidney.—Dr. Alexander Lambert presented a rather rare congenital formation, which had been found in a man fifty years of age, who had been admitted to the hospital with intense dyspnœa and a subnormal temperature. Physical examination showed very rough breathing in the left lung, and hypertrophy of the left side of the heart. He died within forty-eight hours. The autopsy revealed an entire absence of the right kidney and ureter. There was a supra-renal capsule on the left side, but no kidney or ureter in the normal location. A small kidney was found in the hollow of the sacrum. The rectum turned at the brim of the pelvis, passed over the promontory of the sacrum, and out on the right side. The kidney was quite small, being 8 ctm. long, 6 ctm. broad, and two or three centimetres thick. It weighed 72 grammes. No markings could be detected. There was one large, thick ureter. The vessels did not originate from the aorta. The urine had had no casts, and there was but very little albumin. The specific gravity had been quite low. It was remarkable that he could live so long with such a small quantity of kidney tissue.

The speaker said that there had been previously reported to this Society three cases of absence of one kidney, but with the other kidney of normal size, or larger than normal. The left kidney, as was usual, was the one displaced in this case. Usually the left was the one more commonly absent, although not so in the case just reported. That there was a congenital absence of the right kidney seemed clear, because there was but one urethral opening into the bladder, and no vessels from the aorta on that side. Sections of the kidney had been made and examined by Dr. Ewing, who had found the kidney to be made up almost entirely of connective tissue.

Dr. James Ewing asked if the extreme length of the ureter did not point to the fact that the kidney had originally been in its normal position.

Dr. Lambert replied that, as the ureter was only six and a half inches long, he did not think this theory was tenable.

The President said he had found a very similar specimen in the museum of the New York Hospital. In this the bladder was not attached, but the small kidney was misshapen, and the aorta showed a very short renal artery, beginning just above the bifurcation of the aorta. The history of the case was not with the specimen.

Endothelioma of the Pia Mater.—Dr. H. S. Stearns presented an endothelioma of the pia mater. It was located directly in the median line, about half-way between the fissure of Rolando and the anterior edge of the brain. It was 5 ctm. in diameter, about 1½ ctm. thick, and circular in shape. It had been taken from a woman, sixty-five years of age, from whom he had removed a carcinomatous breast on February 8th. She had had no cerebral symptoms. Ten days after the operation she developed pneumonia, and died shortly afterward. The growth in the brain was an endothelioma, and that in the breast a typical carcinoma.

Acute Infectious Disease with Intestinal Lesions.—Dr. James Ewing presented these specimens. The patient was a plumber, seventeen years of age, who was admitted to the Roosevelt Hospital on February 7, 1895. He had a family history of phthisis. The present illness had begun on February 1st with general pains, moderate fever, and considerable prostration. On the second day there was abdominal pain, which was at first diffused, and he had three diarrhœal movements and repeated vomiting. On the third day he developed a petechial eruption, most marked on the limbs. Following an enema he had a large, dark stool, and the next day, after a purge, a stool containing mucus and blood. Up to this time the case had been considered one of appendicitis. On February 12th the abdominal pain became much worse, and on the following day a new crop of petechial spots appeared on the exposed parts of the upper limbs. At the time of his admission to the hospital, the urine had a specific gravity of 1.028, was acid in reaction, and was free from albumin. On February 16th its specific gravity was 1.013, the reaction was neutral, and there was a small quantity of albumin present. On February 18th the specific gravity was 1.015, and the urine contained thirty per cent. of albumin. On February 20th the specific gravity was 1.022, there was sixty per cent. of albumin, and some hyaline and epithelial casts. On February 23d there was sixty-five per cent. of albumin, and a specific gravity of 1.025. His temperature rose to 104.6°, the pulse to 150, and the respirations to 42, and it was evident that there was a double pneumonia and a beginning peritonitis. On the next day the specific gravity of the urine was 1.017, and it contained seventy per cent. of albumin and five per cent. of sugar, with some waxy casts. He died on February 27, 1895.

The history, then, was that of an acute infectious disease of mild onset, with symptoms of moderately acute enteritis, associated with a petechial eruption, occurring in two distinct crops. Death was due to the pneumonia and the peritonitis. The autopsy showed pneumonia in both lower lobes, and a general purulent peritonitis. Throughout the ileum, and in other parts of the small intestine, were numerous petechial spots, and a considerable number of punched-out ulcers without much inflammation in their vicinity. The bases of some of these ulcers were quite thin, but the exact point of perforation was not found. Peyer's patches were apparently normal, and the mesenteric glands were considerably enlarged.

The clinical course of the case, the speaker said, was very similar to that of two cases occurring in Roosevelt Hospital within the past two years, and these latter had been recorded as examples of intestinal mycosis.

Dr. Prudden said he thought that one contribution which experimental pathology had made to gross pathology was, that it was not necessary to have a perforation of the intestine in such cases as these in order to account for peritonitis, for it had been conclusively demonstrated that bacteria could pass through the wall of the intestine when this was in a necrotic condition.

Hypertrophy of the Heart with Fibrous Thickening of the Abdominal Aorta.—Dr. F. Ferguson presented specimens from a case of hypertrophy of the heart. For five weeks previous to the admission to hospital, the patient had suffered from shortness of breath, swelling of the feet, cardiac palpitation, and pains radiating from back around to the abdomen. On admission, the temperature was normal, respirations 28, and pulse 80. He did not improve under the usual treatment of cardiac debility, and he died rather suddenly. The autopsy revealed marked hypertrophy and enormous dilatation of the left ventricle; moderate hypertrophy and normal valves on the right side. The mitral valve was slightly narrowed. The cusps of the aortic valve were very greatly thickened and retracted. There was also a pronounced pericarditis. Areas of atheroma were scattered throughout the aorta, but particularly in the abdominal portion. Here there was a fibrous thickening, possibly due to the enormous hypertrophy of the heart. The liver was of the nutmeg type; the lungs were the seat of the usual cardiac pneumonia; and the kidneys showed chronic passive hyperæmia.

Aneurism of the Superior Pancreatico-duodenalis, with Perforation into the Common Bile-duct.—Specimens of this case were presented by Dr. Ferguson. Only brief notes were given, as it was to be published in detail. The patient was a man of forty-two, and various diagnoses had been made, *e.g.*, pernicious anæmia, duodenal ulcer, carcinoma, and biliary calculi. A clot was found extending from the orifice of the common bile-duct into the ramifications of the bile-duct, and into the liver and gall-bladder.

The President said that Dr. H. M. Biggs had presented a somewhat similar case to the Society, in which there had been a well-defined aneurism at about the same site. His patient had died from very profuse hemorrhages from the mouth and rectum, lasting about three days. It had been remarked by one of those present at the time of the presentation of this specimen, that a German writer had reported four or five exactly similar cases.

Epithelioma Following Skin-grafting.—Dr. E. K. Dunham presented a specimen of epithelioma with the following history: A woman, fifty-three years of age, had abraded the right tibial crest. The ulcer had healed in about one year, leaving an adherent cicatrix. In 1872, the cicatrix broke down, and an ulcer formed which never healed. On March 9, 1894, the foul ulcer was thoroughly scraped, and in May the ulcer, which was granulating, was grafted with skin. In June, 1894, she was discharged "cured," all of the grafts having taken except one small spot. In February, 1895, she was re-admitted, the ulcer having re-opened. At this time it was covered with unhealthy granulations. A portion of the ulcer was excised for examination. The specimen presented an admixture of spiculæ of bone and epithelium, some in nests and some containing pearl bodies. The speaker said he would like to know whether this condition had anything to do directly with the skin-grafting.

Dr. Ferguson said he thought it fairly common for such epithelial tumors to follow injuries, quite a number of years after the injuries. Chronic ulcers on the front of the leg he knew became epitheliomatous in many individuals. He felt that this statement could be verified by the records of any of our hospitals.

The Society then went into executive session.

Stated Meeting, March 13, 1895.

George P. Biggs, M.D., President, in the Chair.

Primary Tuberculosis of the Kidneys.—Dr. H. P. Loomis presented specimens from a man twenty years of age who had been admitted to the hospital two weeks ago. He had been perfectly healthy up to four months ago, at which time he had had an attack of gonorrhœa. Two weeks later his present illness had begun, with daily chills unaccompanied by sweating. He steadily lost flesh and strength up to the time of his coming to the hospital. On admission his temperature ranged between 102° and 103° F. His blood was examined for the plasmodium of malaria, but it was not found. Urination was quite frequent. The urine had a specific gravity of 1.008, was straw-colored, acid, and contained albumin and hyaline casts. He complained of pain in the lower portion of the abdomen, and also on micturition. The case was at first supposed to be one of pyelitis, secondary to a gonorrhœa and inflammation of the bladder. After this the urine was examined for tubercle bacilli, and as these bacilli were found, the diagnosis was made of tuberculosis. No evidence of tuberculosis was found

in the chest. Three or four days before his death his temperature rose quite rapidly. The autopsy was made under great difficulties. The lungs were found to be studded in every portion with exceedingly minute miliary tubercles. The liver and spleen were also studded with these tubercles in a similar manner. The heart was normal. The right ureter was very much dilated with fluid like urine. The kidney on that side was the seat of a chronic tubercular process. The process had been very much more extensive in the left kidney, so that this organ was almost completely destroyed, and the remains of the organ were filled with cheesy matter, which also contained the tubercle bacilli. There was no tubercular process in the testicles and the prostate. The tubercular process in the bladder seemed to be secondary to that in the upper portion of the genito-urinary tract. The case, therefore, was one of primary tuberculosis of the kidneys. The speaker said he could not tell where the infection had gained entrance to the system, nor could he say whether the attack of gonorrhœa had had anything to do with this tuberculosis. It had been claimed that the bacilli sometimes gained access to the bronchial glands, and from there passed to the blood, and so on until the pelvis of the kidney was reached.

Double Suppurating Epididymitis; Ulcers of the Stomach; Calcareous Plate in the Diaphragm.—Dr. George P. Biggs presented specimens from a man who had been admitted to the Hudson Street Hospital on February 10th, complaining of general abdominal pain, more particularly on the right side. No venereal history could be obtained. His temperature was found to be 103.8°, and a few hours later it was 105.4° F. During this time it was not noticed that the œdema of the scrotum was rapidly developed, and that this was localized chiefly in the neighborhood of the epididymis. On the second day he developed violent delirium, with great abdominal tenderness and distention. He was an alcoholic subject. Thinking the case to be one of appendicitis an exploratory incision was made, but the vermiform appendix was found to be perfectly normal. His temperature continued elevated, reaching as high as 107° F., and he died the second day after the operation, or six days after the beginning of the trouble. Just before death he vomited a considerable quantity of thick, bloody-looking fluid. At the autopsy a recent general peritonitis was found, the cause of which could not be discovered at first. The intestinal tract throughout was normal. There was, however, a good deal of swelling in each iliac region, and on incision into those swellings considerable pus was found to have infiltrated the tissues in this region. On the right side the pus had infiltrated the fatty capsule of the kidney and had extended down along the spine and along the inguinal ring and cord to the epididymis. On the left side the infiltration of pus was less extensive, extending up to the promontory of the sacrum and along the cord to the epididymis. These two collections of pus did not communicate with each other, the tissues in front of the spine being perfectly normal. From double involvement of the epididymis, and the retroperitoneal suppuration and peritonitis, it was evident that the original source of the trouble had been a double epididymitis of a very virulent character. The genito-urinary tract was examined throughout and found perfectly normal, and the testicles proper were also perfectly normal. The fresh pus showed large numbers of streptococci, and cultures made from these collections of pus showed pure cultures on one side. It had been noted at the time of his admission to the hospital that both parotid glands were slightly enlarged and tender, but no special importance had been attached to this at the time. The stomach showed two or three quite superficial ulcers along the greater curvature of the stomach, near the pylorus, and on two or three of these was clotted blood, indicating the source of the bloody vomiting occurring just before death. There was a calcareous plate in the diaphragm, which measured three inches in length, two inches in width, and one-quarter of an inch in thickness.

Gunshot Wound of the Heart and Lungs.—Dr. Biggs also presented specimens that had been removed from a man of thirty-five years of age, who had been admitted to the same hospital. He had shot himself, the bullet entering half an inch below, and a little to the inner side of, the left nipple. He was suffering from severe shock at the time of his admission. Signs of fluid and air in his left pleural cavity were apparent, although no distinct pericardial involvement was made out. He lived three days. At the autopsy the course of the bullet was traced with difficulty, owing to the points through which it had passed having been covered over with fibrin. The left pleural cavity contained a moderate amount of air and at least 1,500 c.c. of dark bloody fluid. The surface of the lung was covered everywhere with a thin layer of fibrin. The pericardial sac was distended with fibro-purulent exudation. The bullet had gone through the lower portion of the upper lobe of the lung, had then passed into the pericardial sac, and had traversed the wall of the left ventricle for a distance of about four centimetres. The bullet had entered at the anterior aspect of the left ventricle, about midway between the base and apex. The bullet, after traversing a distance of about four centimetres, emerged, entered the pericardium, and again passed through the lower lobe of the lung, finally lodging between the ninth and tenth ribs. The bullet did not enter the cavity of the heart at all. On the inner surface, opposite the track of the bullet, was found a firm ante-mortem thrombus, about two centimetres in length and one centimetre in breadth at its thickest part. This was due to the fact that the vessels had been sufficiently injured to cause softening through the entire thickness of the wall, and so give rise to endocarditis and thrombosis. From this thrombus an embolus had broken off, and had lodged in the branches of the splenic artery, producing large red infarction, which occupied almost the entire spleen. The splenic vein was also completely thrombosed.

Hypertrophy and Dilatation of the Heart, with Tricuspid Regurgitation and Mitral Stenosis.—Dr. Biggs also presented specimens that had been taken from a boy, eighteen years of age, who stated that for two years previously he had been jaundiced, and had suffered considerably from shortness of breath. On admission his pulse was weak, irregular, and rapid, and had a distinct pulsation. There was also marked pulsation of the veins of the neck, and he was cyanosed. Examination of the heart showed a greatly accentuated second sound, heard more over the right side of the heart, and systolic. The diagnosis was made of tricuspid regurgitation and mitral stenosis. This diagnosis was completely confirmed at autopsy. The mitral orifice was found to be very greatly narrowed. The tricuspid orifice was very large, so that almost four fingers could be passed into the orifice. The points of interest were the great thinness of the left ventricle and marked hypertrophy of the right ventricle. The kidneys only showed the effects of chronic congestion.

Stated Meeting, April 10, 1895.

George P. Biggs, M.D., President, in the Chair.

Tumors from the Choroid Plexus of a Horse.—Dr. J. H. Huddleston presented several specimens from the lower animals. The first specimen was the brain of a horse, with two tumors originating in the choroid plexuses. One tumor was as large as a large English walnut, and the other about three times as large. So far as could be learned, the horse had presented no symptoms until the evening of his death, when he had apparently had a spasm. Sections of the tumor were

exhibited under the microscope. Their structure indicated the growths to be fibro-sarcomata.

Actinomycosis.—The second specimen was the lower jaw of a cow. It had been removed from an animal suffering from actinomycosis, or the disease known among meat inspectors as "lumpy-jaw." The fungus, the speaker said, was prone to lodge in the mouth, usually in the lower jaw, where it works into the periosteum, and finally produces a rarefying osteitis.

Bots from a Horse's Stomach.—The next specimens were bots taken from a horse's stomach. The bots, or larvæ of a kind of fly, are very commonly found in greater or less number in the horse's stomach. They are about half an inch long, and after being swallowed by the horse, attach themselves to the mucous membrane of the stomach, and live there for ten months or more, and then pass out with the excreta. They are not generally supposed to produce any symptoms, although cases have been recorded where they have caused perforation of the stomach and death from hemorrhage.

Pseudo-tubercles in a Sheep's Lung.—A specimen was then shown of the lung of a sheep, containing bodies which resembled tubercles rather closely. They were not tubercles, however, but the embryos of a parasite which had entered the animal through the bronchi.

The Ticks of Texan Fever.—Dr. Huddleston said that the disease known as "Texan fever" was caused by a micro-organism living within the red blood-corpuscles. It was usually found in pairs, but was sometimes found outside of the blood-corpuscle. This parasite gave rise to hæmoglobinuria, and death in a large proportion of cases. The method by which the disease was disseminated had only been quite recently discovered by the United States Bureau of Animal Industry. It had been found that these "ticks" took up some of the blood from infected animals and transferred it to other animals.

Intussusception in a Dog.—The last specimen had been taken from a Siberian "trick dog," who, after having nearly recovered from the distemper, had been taken ill with a form of dysentery. After a few days a tumor had been felt in the left side of the abdomen, and then an intussusception with perforation had been discovered. It was said that intussusception was not infrequent in dogs.

Dr. Reginald H. Sayre said that the horse sometimes exhibited lumps on the body, something like an urticarial eruption in the human subject, which were supposed to be due to bots. This was frequently associated with disturbed digestion, and the animals were with difficulty restored to good condition. Bots were frequently passed in large numbers after the use of brisk purgatives on such animals, showing that the diagnosis of bots was probably correct. If, therefore, as had been said, bots were almost invariably found in the stomachs of horses, why was it that they only exceptionally gave rise to symptoms?

The President said that as the number of these bots varied very greatly, they being sometimes so numerous as to almost coat the interior of the stomach, it was not improbable that the presence of symptoms would be determined by the number of these bots in the stomach.

Dr. Huddleston said that as there were several varieties of bots, this might also explain the occasional occurrence of these symptoms.

Foreign Body in the Vermiform Appendix.—Dr. Warren Coleman presented a vermiform appendix containing a foreign body. It had been removed from a man, sixty-seven years of age, who had died from broncho-pneumonia complicating chronic diffuse nephritis. On opening the abdominal cavity the tip of the vermiform appendix was found lying on the sacral promontory uncovered by intestine, and the end of the appendix was decidedly enlarged. The appendix itself measured four inches in diameter and about one-fourth of an inch in its transverse diameter. The foreign body was found to be a fragment of bone, one end of which was rounded, and from the other end of which projected three sharp points, any one of which would seem to be sharp enough to perforate the wall during a sharp contraction. This piece of bone measured five-eighths of an inch in its long diameter and one-quarter of an inch in its broadest transverse diameter. It had entered the appendix blunt end foremost, and had travelled up as far as it could go. There had not been found the slightest evidence of inflammation outside of the appendix, or within it, except possibly a slight thickening of its wall. The foreign body was entirely surrounded by mucus, and the lumen of the appendix was entirely filled with it. The appendix itself had a mesentery which extended nearly half of its length. The appendix had not been bound down at all.

The speaker said that it would have been extremely interesting if the complete history of this case could have been obtained. Reasoning from analogous cases, involving the bile ducts and ureters, it would seem that at some time previously this man must have had a sharp and more or less protracted attack of colic. Appearances would seem to indicate that the foreign body had been in the appendix for a considerable length of time, for there was a pigmentation of the bone which would have hardly existed at the time it was swallowed. Dr. Coleman said that he had never seen a case of foreign body in the appendix before, although he had made it a rule to carefully examine the appendix at every post-mortem. No fæcal impaction had been found in this case.

The President said he was reminded of a specimen recently shown by Dr. McBurney, who had never seen any such foreign body in the appendix previous to that time. It had been found during an operation for some other abdominal condition. Two small bodies had been felt in the appendix, which had been accordingly removed. Two perfectly fresh and well-preserved grape-seeds were found in the appendix. They had not been at all digested and there was no evidence of inflammation. He had personally seen only one case in which there had been a grape-seed.

Dr. John H. Hinton said that in the old days of the Pathological Society, when Dr. Finnell used to bring specimens to the society, he had presented several specimens from cases of appendicitis, where beans had been found in the appendix.

Dr. S. T. Armstrong said that these two cases were of interest as showing that something more than an extraneous substance in the appendix was necessary to produce appendicitis. The number of these cases was becoming sufficiently great to indicate that our knowledge of the pathology of appendicitis must be revised.

Pulmonary Tuberculosis with Cavity in a Child.—Dr. Robert S. Adams presented a tuberculous lung removed from a child one and a half years of age. The child had been ailing since last November and had been known as "the child with a bottle lung," because of flatness over the lower part of the left lung posteriorly, and a breathing sound at this part almost precisely like that produced by blowing across the mouth of a bottle. The walls of the pulmonary cavity were very ragged. A "smear" taken from the lung showed tubercle bacilli. The upper part of the lung had been apparently but very little affected. The speaker said that tuberculosis was very frequent in the latter part of the first and second years of life, but it was not common to find very large cavities in small children.

Enlarged Spleen; Lobar Pneumonia; Pericarditis.—Dr. Donald M. Barstow presented a spleen taken from a patient who had been brought into the Hudson Street Hospital on April 2d, with a temperature of 102.4° F. and a very rapid and feeble pulse. He was somewhat delirious, and there was marked jaundice of the skin and conjunctiva. The delirium and temperature increased, and he died early in the morning of

April 4th. The history had been obtained only through an interpreter. The man had not been working for eight days, as he had been suffering from pain in the chest, not very definitely localized, and from pretty well-marked dyspnœa. The autopsy was made a few hours after death. It disclosed a lobar pneumonia of the right lung, the lung being entirely consolidated. The pericardium contained twelve ounces of rather thin pus. The heart was normal and the valves competent. Both chambers were filled with blood-clot. The tissue was rather dark and granular. The liver was apparently normal. The spleen measured eleven inches in length, eight inches in width, and three or four inches in thickness, and weighed seven pounds eleven ounces. The kidney showed the degeneration which accompanies lobar pneumonia. There were no other lesions. The cause of the enlargement of the spleen was rather interesting. The spleen pulp was rather soft. There was no sign of acute inflammation externally. The gall-ducts were pervious, and there was no obstruction to the portal vein ; hence, a congested spleen could be excluded. There was nothing in the spleen or in the blood from the splenic vein to suggest leucocythæmia. The man was an Italian, but whether or not he had been long in this country or had recently come from a malarial district, could not be determined. In favor of the theory that there had been an acute inflammation was the fact that the man was profoundly septic, and had a high temperature, and his jaundice was evidently due to some poisoning of the blood. Zeigler says that in acute disease the spleen may be enlarged, even to four times its normal volume. The stomach and peritoneum were normal. The intestines were not opened. It was possible, although not probable, that there were typhoid ulcers in the small intestine.

The President said he could recall at least three instances in which he had found very large spleens in adult Italians, evidently the result of chronic disease, as there were no evidences of disease of the blood or lymphatic glands. Although in these cases the spleen had not been particularly pigmented, he had felt that the splenic enlargement had been due to malarial infection.

Myelitis and Rupture of the Bladder.—Dr. Henry Power exhibited some photo-micrographs, taken with high and low powers, and also some slides under the microscope from a case of myelitis, complicated by rupture of the bladder. Death had occurred from the shock of the rupture. The history of the case was very meagre. There was a chronic myelitis, distributed principally through the dorsal and lower cervical regions. The interesting part was the condition of the veins and arteries. The former were almost normal, whereas the media and adventitia of the veins contained a large quantity of round cells—whether leucocytes or new connective-tissue cells could not be determined. Gowers and Zeigler gave a general description of such a condition, without distinguishing between the veins and arteries.

A Remedy for Tape-worm.—Dr. J. H. Newington, writing to *The Lancet*, says that many years ago he was giving a patient a mixture as follows : Hydriodate of potass., gr. xxxvj. ; iodine, gr. xij. ; water, ʒ j.—ten drops three times a day in water. The patient unexpectedly passed a tape-worm eleven yards long, dead, of which there were no previous symptoms. He has since given the same medicine successfully in two or three cases. The last patient came to him about three years since and stated that he had suffered from tape-worm for two years and was constantly passing pieces of the parasite, but could not get rid of it. Dr. Newington gave him the same medicine, and after a short time he passed a mass of tape-worm, dead, and there has been no return.

Clinical Department.

A DELUSION OF STIFFENED EXTREMITIES TREATED BY SUSPENSION.

By EDGAR J. SPRATLING, M.D.,

FISHKILL-ON-HUDSON, N. Y.

In 1880, a patient was admitted to the Middletown State Hospital, adjudged insane by the court upon a charge of assault of the first degree. He was then in a state of profound depression, being at all times morose and taciturn. Until 1885 he worked about the place, making himself more or less useful, as patients can do, then came some trivial misunderstanding with the officials, according to his own statement, concerning a persistent pain in the lower vertebræ. From patient's account and the position afterward assumed and fixedly maintained, this pain was most likely coxalgia. Upon this he went to bed, where he remained constantly, refusing to make any explanation of his symptoms, or in any way seek or accept the medical and other aid offered him by the officials. He states that the pain was constant for months after taking to his bed, until in fact the habit of walking was entirely lost, after that no effort was made to walk, but he would lie quiescent till disturbed by some patient or other person, whom he would then assault most maliciously. Those in authority were always to him especial objects of attack and vituperation ; he seeming instinctively to dislike any exercise of authority, thinking that his own peculiar prerogative.

The delusion of not being able to walk was now firmly fixed with him. He refused to even make an effort ; always asserting that he could neither place his feet in juxtaposition, nor stand erect. He was equally positive that he could not in any way make use of his hip- or knee-joints.

After being a never-ending source of annoyance to the officials his transfer to the Matteawan State Hospital was secured. He was admitted here on a stretcher, in fairly good general health, in a bright mental condition. This was in 1892. He remained continuously in bed, going out once each day to the water-closet, dragging himself on the floor, or crawling by the aid of chairs and tables. Various efforts were made to get him to sit in an upright position in a chair, but he would persist in maintaining the rigid straight position, thereby slipping out on the floor. These efforts or persuasions to make him try to walk met with no encouragement. He would in no way co-operate with the physician, even becoming angered with any suggestion of regular treatment. This lasted till the spring of 1895, making actual time spent in bed over eight years.

On March 26th, after electricity and massage had been tried to a limited extent with no indication of possible ultimate good, it was decided to try suspension by a Sayre's apparatus. The first trial lasted twelve minutes. The time he remained suspended was increased five minutes each day, and after each time he was required to remain standing from twenty to thirty minutes in the middle of the ward hall, where he could grasp no object by which to steady himself. Of course the patient considered all this, at least so he expressed it, as malignant persecution, and protested most vigorously both by mouth and by sheer strength, fighting tooth and nail.

After two weeks of this treatment daily it was discontinued as being no longer indicated, he being then willing to exercise in walking a given length of time each day. He was never allowed a crutch or walking cane.

On April 22d, he went to the table, up and down steps, for dinner, the first time in over eight years. He now goes regularly to his meals, is friendly and good-

natured, saying that the treatment was a benefit to him. He helps with the ward work, and is in every way a changed man, standing and walking erect and firm, rarely or never indicating any inconvenience.

Was it the forcible overcoming of his delusion, or was it the actual surgical benefit that did the ultimate good?

There were two physicians, Dr. R. B. Lamb and the writer, employed in the suspensions, one appearing as the aggressor, the other as the moderator as it were. To the latter he would confide his sensations in the hope of getting his interference. In this way we could regulate the management of the whole treatment to the best good. This dual method is, I think, very often useful in the management of any fixed delusion, giving, as it usually does, the physicians a decided advantage.

Matteawan State Hospital.

THE LARGEST CATHETER, ALWAYS.

By FERD. C. VALENTINE, M.D.,

NEW YORK.

GENITO-URINARY SURGEON, WEST SIDE GERMAN DISPENSARY, ETC.

It seems surpassingly remarkable, in view of all that is written on catheterization of the urethra, that so many otherwise exceedingly well-informed, skilful general practitioners will persist in endeavoring to pass small catheters. A case brilliantly illustrating this error was brought to my attention May 22d of this year.

A. B——, aged sixty, a hale, well-preserved man, visiting friends in Newark, on Sunday, May 19th, found no convenience for urination, and never having had any difficulty before, reserved emptying his balder until he would reach his home in New York. On arriving there some hours later, he discovered that all efforts at extruding urine proved absolutely futile. From Sunday night to Wednesday, several physicians had endeavored to relieve him with small instruments. They succeeded only in giving the patient much pain and drawing considerable blood, whose quantity doubtless was much exaggerated in the family's statements.

On Wednesday evening Dr. Ludwig Kohn was called and, finding the patient in the condition to be expected after passing no urine for three and one-half days, demanded a consultation. Dr. Henry Roth came for me. His history and description of the case caused me to go with him prepared for supra-pubic puncture at least.

On arrival at 10.30 P.M. I found the patient exactly as described by Drs. Kohn and Roth, the salient points being a very much distended bladder, whose fundus reached apparently to the umbilicus, a prostate hypertrophied to about the size of a large fist, with a well-defined middle lobe, and a roomy urethra with no less than half a dozen lacerations in its membranous part. Before proceeding to more serious operative measures, we naturally determined to essay the passage of a catheter. The meatus appeared as if it would comfortably admit a 10 American. On taking a Tiemann's 12, velvet-eyed, soft catheter, the comparative ease with which it passed into the bladder would be surprising to those not accustomed to such experiences.

Dr. Kohn, who continued treating the case, informs me that he had no difficulty in increasing the size of the catheters used by one number daily, having reached No. 15 on Saturday, May 25th, and that the patient is in exceedingly good condition. Manifestly, if a large catheter had at once been used, much suffering would have been spared this man.

It is a rule with me to urge upon those who favor me by attendance upon my clinics the following apparently paradoxical rule: "In retention from any cause, compare the meatus with your catheters. When you have determined upon the size which promises to pass, make your first endeavors with two sizes larger."

Posner[1] says in this connection: "In the vast majority of instances, the careful introduction of soft, elastic instruments will accomplish the desired end. At all events these instruments are recommendable to those who have not acquired considerable skill and practice. At least no injury can be done by them."

While the case above sketched contains nothing new, I feel convinced that other genito-urinary specialists will agree with me in urging upon general practitioners that the greatest possible safety lies in always using the largest possible catheter.

242 West Forty-third Street.

New Instruments.

THE OPEN-AIR TREATMENT OF HIP-JOINT AND SPINAL DISEASE.

By W. W. BREMNER, M.D.,

TORONTO, CANADA.

LATE ASSISTANT SURGEON, HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK.

It is now almost universally admitted that hip-joint and Pott's disease are of a tubercular nature, and that in many cases of these diseases, at some period or other in their course, recumbency becomes a necessity in the treatment. Now, it is not proposed for an instant here to lay down any rules as to what cases need recumbency, but it is desired to lay before the profession a simple method by which recumbency, with any advantage it may have, can be obtained without the counter-balancing evils which attend it when used in the general way by confining a patient to bed.

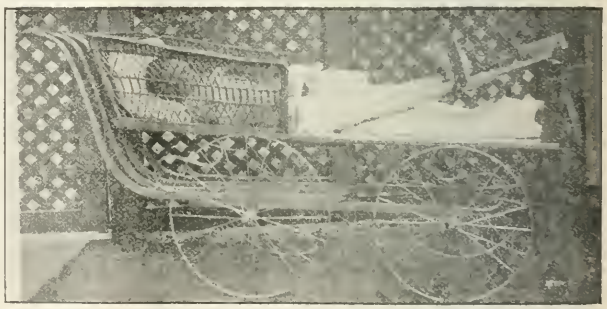

Fig. 1.

A light carriage with wicker-work sides, rubber tires, and well-tempered springs is made of a length suitable for the patient, allowing for at least three years' growth, and it is surprising how a child will grow on such a carriage in the fresh air and sunlight. A frame of hard-wood, of a length suitable for the weight of the patient, is then made; good ash (three-quarters by two and a half) is strong enough for a child under five years of age; this frame should fit snugly inside the wicker-work of the carriage and be covered with strong canvas laced beneath to keep it tight. The canvas can be made in three sections, one narrow in the middle for removal when the bed-pan is required; a better plan, however, is to use stiff brown paper for the motions and a bottle or small flat dish for the urine, according to sex. An apron, reaching from the axilla to the pubes, is sewed on either side of the canvas and fitted

[1] Therapie der Harnkrankheiten, published April, 1895, in Berlin.

with buckles to keep the patient in position ; in addition, it is well to have leather straps to hold down the shoulders ; the most simple way is to tack them on the sides of the frame and let them cross the chest diagonally at the top of the sternum.

The frame can be lifted in and out of the carriage as desired, but in practice it will be found very convenient to keep the patient in the carriage day and night. In warm weather a light, soft quilt under the patient or a narrow pillow is all that is required. In cold weather a small, soft mattress or a couple of pillows should be placed between the frame and the carriage to keep out the cold.

In spinal disease pads of felt should be stitched on the canvas on either side the kyphosis, to prevent undue pressure on the spinous processes. In general, it is best to fit the patient with a suitable brace as well as the carriage.

In all cases of hip-joint disease, and in those of Pott's disease where there is psoas contraction, means are provided for counter-extension by a light but stiff steel bar bent across the frame just above the pubes, and removable at pleasure by unscrewing two bolts to which perineal bands are attached by means of buckles. (See Fig. 2, which represents a child seven years of age with very severe hip-joint disease, in the upright position, which may be given at pleasure and which is very convenient when taking food.) Fig. 1 shows the same child in the horizontal position. In both figures the uprights with cross-bar at the bottom of the frame are clearly shown. These permit of extension being made in the angle of deformity, which is most necessary in order to avoid great pain. The child shown in figures, when treatment was commenced, had about thirty-five degrees of flexion and twenty degrees of adduction. In six weeks, with only eight pounds of weight, the limb was straight. The bar can be lowered one-half inch every day for a few days, and the splint on which the limb lies abducted a little at about the same intervals. Light boards are fitted on either side of the carriage to prevent the clothes falling out. During the day counter-extension is made by the perineal straps, at night the pressure on the perineum can be relieved by elevating the foot of the carriage.

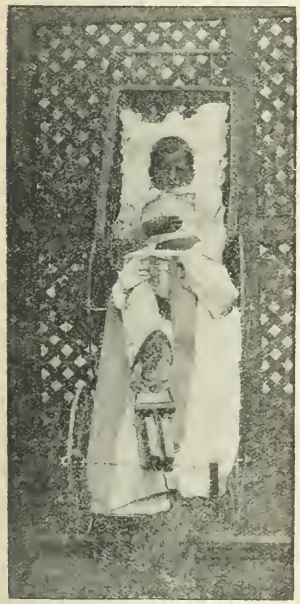

Fig. 2.

This method has been tried for over a year in several cases of acute hip-joint disease, with most satisfactory results in every way, especially in regard to the general health. As far as I can find out from the literature at my command, the method is new. It is applicable to both private and dispensary patients, as no difficulty is found in getting most of the dispensary patients to pay a small monthly rent for such a carriage, and even in hospitals it might be used with advantage where there is an open-air balcony or veranda on to which the carriages could be wheeled.

These carriages are very inexpensive and can be made by any bassinet manufacturer.

39 Bloor Street, East Toronto.

A NEW ADENOID FORCEPS.

By WILLIAM P. BRANDEGEE, M.D.,

Assistant Surgeon, Manhattan Eye and Ear Hospital, Throat and Nose Department.

With some hesitation, because of the long and varied list of instruments which have already been devised

for the removal of adenoid growth in the vault of the pharynx and the posterior pharyngeal wall, I present this adenoid forceps.

This instrument was designed, however, to eradicate certain defects in construction which make an adenoid forceps inefficient for operative purposes. The instrument is an evulsion and cutting forceps, strongly built and smooth on all surfaces that are brought in contact with mucous membrane. The cutting blades meet in the median line but do not cross, work laterally, and cut not only on the superior but also on the posterior surfaces.

As the blades do not cross, a space is left for the uvula so that it cannot be damaged in the course of the operation. The instrument can readily be taken apart and rendered aseptic. This forceps is introduced closed and only opened when the vault of the pharynx is reached. My thanks are due Mr. E. B. Meyrowitz for the workmanship and skill displayed in the construction of the instrument.

36 West Thirty-third Street.

A PHIMOSIS CASE.

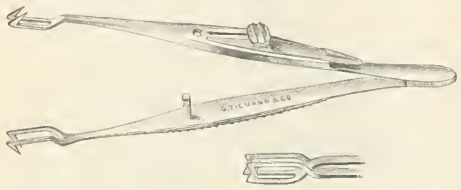
By R. W. KNOX, M.D.,

Houston, Tex.

Messrs. Tiemann & Co. have made for me a phimosis forceps and also a prepuce-retractor. These instruments they have included in a small aseptic case containing scissors, hypodermic syringe, Grove director, narrow-bladed bistoury, and four small bottles for carrying needles, cocaine tablets, and two small sizes of silk ligatures. The phimosis forceps has been previously described. The retractor gives great assistance in applying the forceps accurately, and without the aid of an assistant. It has spring blades with double

tenaculum points, which are concealed when the instrument is closed. The cut gives a better idea of its mechanism than is possible by a description. I operate as follows : The patient is placed on a table, and the parts made as aseptic as possible with soap and water. A rubber band is placed at the root of the penis, encircling that organ in order to prevent hemorrhage during the operation, and also to confine the action of the cocaine. I find about ten minims of a four per cent. solution of cocaine injected in different points of the skin sufficient to produce complete an-

æsthesia of the parts to be incised. The retractor is now introduced a short distance within the foreskin, the blades allowed to spring apart by releasing the slide catch, and gentle traction made. The forceps is now applied and tightened at the most desirable point. The bistoury then removes the engaged prepuce with



a single stroke. If the mucous membrane is not sufficiently removed with the skin, the excess can be quickly cut away with the scissors. The foreskin can be removed much more quickly and accurately in this way than is possible by the use of knife and scissors alone. The case has the advantage that everything necessary for the operation is always at hand and can be readily carried in the pocket.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE PRINCE AT EPSOM COLLEGE—THE COLLEGE OF SURGEONS ELECTIONS—THE MUSEUM—POLICE SURGEONS—CAMBRIDGE SUMMER SCHOOL—CHLOROFORM FATALITIES—APPOINTMENT OF QUEEN'S SURGEON, ETC.—DR. RUFFER.

London, July 13, 1895.

Epsom was adorned in holiday attire to receive the Prince and Princess of Wales on Monday afternoon, and the inhabitants indulged to the utmost their demonstrations of loyalty. The Prince laid in a workmanlike manner the foundation-stone of the lower school which is to be added to the Royal Medical Benevolent College, mentioned that he remembered accompanying his father, more than forty years ago, to open the college, and expressed the hope that the new buildings may add in every way to the usefulness of the institution. The royal party inspected the college before leaving, amid renewed demonstrations of loyalty. The school has maintained a good position and grows in favor. Last year an act of Parliament was obtained under which the Council can open it to all classes—the special privileges of medical men's sons being reserved. It is thought that this will be better for the boys than restricting it to one class, the admission of representatives of other professions tending to widen the sympathies and enlarge the ideas. I wish it were possible for the fees to be further reduced in the case of medical men or their widows, who, though their sons are eligible for the foundation, still find education expensive.

The elections to the Council of the Royal College of Surgeons had unusual interest, as this was the first occasion on which voting papers were distributed to all the fellows. Of these 621 used their papers, and 60 voted in person. Thus upward of 400 fellows did not vote. In view of the fuss that has been made about the privilege of the fellowship, this is not a result to boast of. Perhaps the non-voters would willingly see the enfranchisement of the members. Surely these last, as qualified surgeons, might be entrusted with a vote for councillors, and perhaps for the president. There is considerable discontent at the canvassing carried on at this election, but what is to be expected in a small, exclusive constituency? Still the majority are shocked at the unblushing electioneering tactics in a body boasting of its high tone and academical distinction by examination. Outsiders say F.R.C.S., Exam., is not a synonyme for a gentleman nor an academical distinction either, as the term is usually understood.

After the election there was a display of the many interesting specimens which have been added to the museum during the past year.

It seems likely that recognized police surgeons will be appointed to examine prisoners arrested on certain charges. The matter was pressed on the Home Secretary early in the year, and before resigning Mr. Asquith issued a circular letter to certain authorities, pointing out the advantages of such appointments. Skilled evidence is certainly important in many cases and should be obtained at the earliest moment. Closely connected with this subject is a strange fact that came to light at an inquest lately on the body of a woman found in a canal. A policeman deposed that he found indications of death from drowning, that he had the body taken to the woman's house, where he had all her clothes removed, and looked for bruises or signs of violence. Surely this policeman went beyond his duties, and should have been sharply taken to task, instead of permitted to give evidence which it is a medical man's place to give.

The summer school at Cambridge for qualified men has afforded a pleasant week's outing with scientific lessons to eighty members, who have been regaled with lectures, demonstrations, and exhibitions, and provided with quarters and good fare at moderate charges. The idea seems to have "caught on," and will, perhaps, prove profitable to both professors and students.

Death from chloroform seems at times to come from recklessness. A young surgeon inhaled it to assuage the pain of sciatica, and seems to have fallen forward when insensible and so taken a fatal dose. Another man is said to have regularly taken chloroform for months past. At length, as might have been expected, he paid the penalty of his rashness with his life. Though not a doctor, he seems to have had no difficulty in obtaining a constant supply of the anæsthetic.

A sad case, apparently of abortion, has been the subject of judicial inquiry and much medical conversation. A graduate whose name had been removed from the Register had been consulted, and a registered man saw the patient and gave a certificate of death. He will probably have to appear before the Medical Council, for, surely, "covering" a man who has been removed from the Register is as bad as doing so for one who has never been on it. Unless further protection be obtained for those who are registered, there will surely be further abuses.

Sir P. Smyly has been gazetted Surgeon to the Queen in Ireland, in succession of the late Sir George Porter. The friends and admirers of Sir G. Porter propose to raise a permanent memorial of his services to the public and the profession. Mr. Lentaigne, of the Mater Misericordiæ Hospital, has been elected to succeed him in the Council of the Dublin College of Surgeons.

Dr. Ruffer, in his investigations on antitoxin, unfortunately inoculated himself with diphtheria. He was treated with serum, and has happily recovered after a severe illness. This is another illustration of the dangers incurred in the course of bacteriological researches.

The Cost of Influenza.—At a meeting of one of the large English insurance companies it was shown that more than six hundred thousand dollars had been paid out for deaths due to influenza.—*Maryland Medical Journal.*

A French Medical Authority asserts that death caused by a fall from a great height is absolutely painless. The mind acts very rapidly for a time, then unconsciousness ensues.

ON THE PHYSIOLOGICAL ACTION OF PERIODIC INDUCED CURRENTS.

To the Editor of the Medical Record.

Sir: If Dr. Goelet had been content to simply reiterate his altogether untenable statement that his permission was asked for the privilege of winding on a single spool certain lengths and thicknesses of wire, I should have been content to allow him the last word of the discussion; but as he not only denies my priority in essentials, but indulges in specific contradiction, I beg to be allowed in proof of my claim to offer the following letter:

"Dr. A. D. Rockwell.

"Dear Sir: In reply to yours of July 15th I would say that as far back as 1884 we constructed for you a coil far exceeding in length our ordinary coils, to illustrate your paper 'On the Induction Coil; its Varieties and the Differential Indications for their Use,' and in 1889 still another, of five thousand feet, made up of coils varying in lengths, and almost identical in the different sizes of wire to that of the apparatus under discussion.

"Very respectfully,

"T. F. Livingstone,
for the Kidder Mfg. Co."

It was on experience with these coils that I based my article on the "Different Physiologic and Therapeutic Properties of the Induced Current of Electricity" (Medical Record, February 14, 1891).

Dr. Goelet seems to think that the important thing is some exact number of yards in each individual coil, and because he suggested a few different numbers, requiring only a knowledge of figures, has the assurance to designate as the "Goelet Coil" a coil the essential features of which were well understood and had been thoroughly described before Dr. Goelet had begun to interest himself in electro-therapeutics.

A. D. Rockwell, M.D.

July 17, 1895.

SOME ASPECTS OF THE NEW WOMAN FROM A MEDICAL STAND-POINT.

To the Editor of the Medical Record

Sir: "The new woman" is at present merely the butt of the humorist, but I am inclined to think that to the medical profession she presents an interesting study. For many years female dress has been a *bête noir* to the doctors, and yet, despite all that has been written and said on the subject, woman, lovely woman, has had her way, and if there is to be a change it will be brought about in her own way and by herself. Concerning tight-lacing I shall say nothing, for so much has been said and written on the subject that it has become nauseous, and the evil is self-evident. But there is another evil connected with woman's present style of dress which has been pretty well ignored. I allude to the skirt. I allow that it is graceful and capable of a great amount of ornamentation, but it is unhygienic in every sense.

How often when the icy blasts of winter have been blowing with hurricane force have we seen female pedestrians clutching at their skirts to prevent them from being blown over their heads, and how often have we seen those same skirts inflated, not like a balloon with hot but with cold air. In fact, they are too often mere traps for collecting cold air. The pelvic organs are well supplied with blood-vessels, and it must follow that when the parts are suddenly chilled the blood-supply is temporarily impaired. To say such a thing is not harmful is, of course, absurd.

What is true of the full-grown woman is doubly true of her younger sister with shorter skirts. Now suppose the latest fad, bloomers, becomes the general dress of woman, all this will be done away with. The pelvic organs will be well protected from rapid changes of temperature. There will not be alternating congestion and anæmia. There will be a general tone given to the pelvis which modern dress prohibits.

Now as to the much-discussed question, bicycle riding for women. I doubt whether it is the best way of taking exercise, but I do think that it may be, indirectly, of incalculable benefit to the female race. It is undoubtedly a most fascinating pastime, and on that account many a woman will be out riding, taking in fresh air, exercising her whole muscular system, when, did she not have her wheel, she would be sitting in the house reading some novel or engaging in some sedentary occupation. Why is it that at least seventy-five per cent. of our patients are women? Has a curse been laid on the sex which condemns them to a greater share of ailments. It looks so, and laymen will say that childbirth is the cause, but it is nothing of the sort. Do mares, cows, etc., fall ill oftener than the males of the same species? No. Why? Because their hygienic surroundings and habits of life are the same. Childbirth is a physiological act, and directly it impairs health it becomes pathological. We know that the higher we go in the scale of so-called civilization the more neurotic the individual, and as society demands that its female members should do no work, so there follows a life of indolence with lack of muscular development. The new woman is changing all this. She is engaging in out-door exercise in very many different ways, and to enjoy this exercise she has had to change her style of dress.

Neurasthenia is alarmingly prevalent among our women, and, for my part, I believe it is due as much to lack of protection to the pelvic organs from climatic change as to anything else, and the next cause on the list is lack of proper, healthy exercise. A woman will sit in the house all day and at nine o'clock at night go out to a dance. She will waltz until she is in a perspiration all over. She will be very solicitous about her shoulders, but will forget that the cool air will penetrate to the pelvis, so she throws a shawl over her shoulders and goes out into the night air to get cool. She does get cool, especially the pelvic organs. The next day ovarian pain sets in, perhaps a cellulitis develops. She has a headache; the doctor comes and says, "You have caught cold," but no word of advice about avoiding cold to the pelvis. Neurasthenia supervenes. A young woman stands in a store all day; at night she is tired; she cannot find enjoyment in walking. To hire a horse is beyond her means, so she sits down and reads; in a short time she becomes hysterical and neurotic.

All this can be remedied by following the lead of the new woman in her rational dress and exercise. Of course, moderation must be exercised in all things.

I am inclined to think that the medical profession may do much in advising, or rather, approving, such measures, but I suppose that where woman is concerned we must fold our hands and say, *Che sarà sarà*.

W. H. F. Miller, M.D.

Clifton Forge, Va.

Signing One's Own Death Certificate.—In an Italian town the death took place of the communal medical officer, one of whose duties consisted in visiting the dead in the public institutions, and in writing death certificates. Among his papers was found his own death certificate, with the disease from which he suffered duly recorded, the certificate being complete in all particulars save the insertion of the date of his death. When, therefore, the new medical officer appeared on the scene, all that was deemed to be necessary was to fill in the date, and the certificate was then regarded as valid.—*Medical Press.*

MODERN GREEK AS AN INTERNATIONAL MEDICAL LANGUAGE.

To the Editor of the Medical Record.

Sir: In the *British Medical Journal* for May 18th, the fact is noted that Dr. Galabin's "Guide to the Diseases of Women" has been translated into Greek by Dr. Luke G. Nipellos, of Athens. In view of the fact that this language is urged as the international language of medicine, it is interesting to see some of the difficulties of transliteration. For instance Σῦδναμ for Sydenham, Δάγκαν for Duncan; Sir John Williams and Hodge are left in Roman characters. Many words, as enucleation, decidua, prolapsus, gutta-percha are placed in brackets, after the Greek rendering, so the reader will be sure of what is meant. Some names of drugs, such as carbamide of quinine are untranslatable. Now, sir, if a modern Greek in his own study, with no limitations as to time, with access to dictionaries, vocabularies, and the like, makes such poor work of translation, what can we expect of American or English physicians who would have to speak extemporaneously, as in discussing papers? Yours truly,

George W. Smith, M.D.

Chicago, Ill.

[A modern Greek in his own study is not necessarily a master of the difficult art of translation, and the capabilities of the language should not be judged by the result of his efforts. Moreover the necessity of transferring bodily some foreign words is no more of an argument against the employment of Greek than is the common use of many English medical terms by French writers an argument against the adoption of French as the universal language.—Ed.]

THE CONDUCT OF THE PHYSICIAN IN A CASE OF CRIMINAL ABORTION.

To the Editor of the Medical Record.

Sir: In Mr. Robert C. Taylor's reply to the Medical Society of the County of New York, in regard to the status of the physician when called to cases of abortion, I read the following: "If he receives a call to attend an urgent case he cannot decline it, even though it be suspicious."

Is this law peculiar to the State of New York? It certainly differs from what I have seen heretofore. I was taught that a physician had a right absolutely to refuse any or all cases. That the fact of his being a physician did not compel him to assume undesirable calls. But if a call should be answered to attend an obstetric case, or an urgent case, he must remain and see the case through, or see that some other physician was in attendance before leaving the case.

When a physician answers a call he enters into a contract with the patient—a preferred contract to give his reasonable attention, such attention as the case requires. It goes without saying that someone must attend these cases of criminal abortion, but it seems to me to be unjust that respectable physicians should be obliged to entangle themselves in these cases.

Mr. Taylor says: "The duty of the physician in these cases relates to himself," *i.e.*, self-protection.

Now, how many physicians have taken the trouble to inform themselves in regard to the law in relation to the procuring of abortion? I think the statute reads about the same in the several States, viz.: "Any person who administers a drug, or performs an operation upon a woman, whether she be pregnant or not, for the purpose of procuring an abortion, unless such be advised by two physicians in order to save the life of mother or child, or both, is guilty of felony." In some States the clause "quick with child" is inserted.

A physician who assumes sole charge of one of these cases is very imprudent. The question arises, how am I to know that the case is due to a criminal operation, or to accidental or so-called natural causes?

In nine cases out of ten, if the woman knows she is about to die, she will tell all she knows about the case, and the attending physician should get a dying declaration. Be sure that she knows she is going to die, and what she says will be accepted by the court without question. It is the cases which die that cause trouble for the attending physician.

I suppose professional abortionists will ply their vocation as long as society demands that they exist. The daily and weekly papers insert their advertisements, and every school-boy and girl knows what they mean.

If this abominable business is allowed to be carried on, and is winked at by the public and officers of the law, let the public suffer, and not the representatives of a respectable profession, who are in many cases literal representatives of the Good Samaritan, giving time and money to alleviate the sufferings of humanity.

That they should be obliged to suffer for the crimes of those who are aided and abetted by society is a blot upon what is called a Christian civilization.

William H. Russell, M.D.

Ipswich, Mass.

THE COUNTRY PRACTITIONER.

To the Editor of the Medical Record.

Sir: Most of our medical journals are filled with articles by our city brethren of the profession, and the country practitioner does not seem to be heard from to any great extent.

The surgeon, the laboratory physician, the college professor, hospital doctor, and the specialists are the ones who generally give in their experiences through the columns of our journals, and while the articles are excellent in their way, some of them are not much help to us country practitioners in our work, embracing as it does everything in medicine from colds to small-pox and paresis, and everything in surgery from ingrowing toe-nails to laparotomy. Long reports of hip-joint operations or rare cases of skin diseases, and laboratory experiments to settle tweedledum or tweedledee of certain bacilli, are nice in their way and very interesting reading, of course, but it does not always seem to suit our case. It may be that we will have to do one hip-joint amputation in a lifetime, but the chances are that we will not, and if there are only a very few cases of the rare skin disease on record, it is hardly probable that we will make a living by our knowledge of that particular disease, however interesting it may be; and we do not see that it makes a great deal of difference in the welfare of that case of pneumonia whether the bacilli which produce it thrive best on gelatine or common boarding-house hash. Of course, these things must be known and studied. They make excellent dessert in our reading course, but they are not the substantial fare that helps us most as individual country doctors, with our many shades and phases of diseases of the more common type. We have no specialist at our elbow, nobody to send our patient to if he develops disease not exactly in our line, but must know everything ourselves and do everything ourselves. If we must know everything we cannot hope to know all of everything, so we have only time for facts about things of use to us in our work. The deeper questions of pathology, bacteriology, special operations, and new theories, we leave to our city brethren; and while we are always thankful for their labors, we cannot help but sometimes wish that they would not be continually startling us with new discoveries before they are discovered, and new inventions before they are invented.

We of the rural districts are expected by our patients to do a great many things. We are expected to pull a tooth for twenty-five cents, and do it better than

a dentist; "stop" typhoid fever at once; to make lines that erysipelas dares not cross; to cure heart disease, foretell the weather, and know what is good for bots in horses. We are expected to know what makes the baby cry without seeing it, and to send medicine by John for female trouble; to cure rheumatism with liniment and "piles" with "salve;" to "break the measles out," and dry the consumptive cough up.

Needless to say we do not do all this, but no amount of explanation will always make it clear that it was not our duty to do it.

If we had a diploma from the best medical school in the world, and had carried off the honors of our class, and were not gray-headed, we would very likely be pitied because we had not had as much experience as the old doctor in the neighboring town, who had been a nurse in the army for six months and had practised for twenty years, never having seen the inside of a medical college.

We can't telephone for an instrument and get it in a few minutes in an emergency case, but must operate with what we have, or make something to answer the purpose; yet in spite of all these things we manage to overcome the difficulties and get along fairly well, and some of the brightest names on the roll of honor of our profession are some of these same country practitioners, men who have conferred lasting benefit on their fellow-men. Still it is often noticed that the wreath of honor is often held from their living brow and afterward placed on their grass-grown graves. The picture, too, has sometimes a pleasant side, painted with brighter colors; but whether his life be bright or dark, grave or gay, all honor, say we, to the patient, toiling, enduring servant of the sick and suffering—the country practitioner.

CLEMENT C. COLLINS, M.D.

ROACHDALE, IND.

RECIPROCITY IN REGISTRATION.

[TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of July 20th "A Country Doctor" says: "I object to the methods of such States as Alabama, California, District of Columbia, Maryland, New Hampshire, Vermont, Virginia, and Wisconsin, where the examination, which is not always required, is conducted by the various medical societies."

As far as regards Virginia, both of these statements are incorrect: the examination by the State Board is always required, and the said examination is not conducted by the "various medical societies."

In justice to the Virginia Board the following facts should be stated: Virginia has had in operation an Examining Board since 1888. Said Board consists of three from each congressional district, two from State at large, and five homœopaths. These are appointed by the Governor of the State from a list of names placed before him by the Medical Society of Virginia, as being reputable physicians and learned in their profession. The homœopathic members are chosen at the option of the Governor. Boards serve four years and have examined, up to date, 887; licensed, 626; rejected and withdrawn, 261; percentage of those successful, 0.705.

The "Country Doctor" is right in having put forward the "Reciprocity in Registration," but it would seem rather extreme for a member of the profession in a State having a State Board of Registration only since July 9, 1895, to be offering uninstructed criticisms upon the methods of other States having Examining Boards in operation for many years, and with a percentage of rejections of thirty as a sample of the thoroughness of the test.

In conclusion, the writer may remark that he passed said examination in Virginia in 1892, and regards it as rigid, but fair. We are glad that Maine is setting her standard high, but "reciprocal registration" is a great way off as yet.

VIRGINIA COUNTRY DOCTOR.

WOODSTOCK, VA., July 24, 1895.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 27, 1895.

	Cases.	Deaths.
Tuberculosis	48	119
Typhoid fever	13	7
Scarlet fever	45	5
Cerebro-spinal meningitis	2	5
Measles	170	18
Diphtheria	174	28

Vicarious Menstruation through the Lungs and its Relation to Tuberculosis, with Remarks on the Treatment of Pulmonary Hemorrhage.—Dr. Kober describes the case of a girl of nineteen years with a tuberculous family history, who had severe hemorrhage from the lungs at the menstrual period, without previous signs of pulmonary disease. The menses proper lasted only a few hours, but the pulmonary bleeding continued for three days with great severity. The bleeding then subsided, after nausea and vomiting had come on, and these latter symptoms lasted some days longer. During this time signs of pneumonia appeared in both bases, with mild general symptoms. In about ten days the patient seemed perfectly well. At the next period a similar set of phenomena appeared, but recovery was not complete. The patient was treated for tuberculosis, although bacilli could at no time be found. Efforts were made at the same time to bring on uterine hemorrhage at the next menstrual period, but in vain, and a third time pulmonary hemorrhage appeared, the amount of blood being less than at the former periods. Vomiting, fever, and a fresh pneumonic attack followed. The cough remained, diarrhœa appeared, loss of flesh and strength, with night-sweats and high temperature, varied the picture, and in four months from the first hemorrhage the patient died. Tubercle bacilli could not be found up to the last. Kober thinks the patient had tuberculosis at the time of the first hemorrhage, and that this was the cause of the vicarious menstruation, the lung forming a *locus minoris resistentiæ* which suffers in the high arterial tension of menstruation. An interesting fact is that no remedy seemed to check the hemorrhage, but that each of the three attacks was cut short by nausea and vomiting. This recalls the treatment of Graves and Trousseau, the former using ipecac in nauseating, the latter in emetic doses. Kober proposes a combination, first causing vomiting, and then keeping up nausea by small doses of the remedy. The cause of the natural cure Kober does not explain, but suggests irritation of the vomiting-centre by lack of oxygen from loss of blood, or in a reflex way by the blood in the alveoli.—*The American Journal of the Medical Sciences.*

The Pulse in Insanity.—Abnormal sphygmographic tracings are to be found at some stage of the disease in the vast majority of cases of insanity. They are due to affections of the cortical and spinal motor and vasomotor centres, to various lesions of the sympathetic, to disorders of the pneumogastric, to peripheral and central vascular changes, to degenerations of central organs, to toxic agents in the blood, to auto-intoxications, to cachectic and diathetic conditions, to cardiac

lesions, and to a great variety of intercurrent causes. These abnormal pulse-tracings vary much in different kinds of insanity and in different individuals suffering from the same form of mental disorder, and they are best classified according to the actual physical status of the patient and the etiology and stage of the mental disorder. No one sphygmogram is pathognomic of any particular form of insanity, but there are certain general types of tracings which are found in one form of mental disease and not in another. Sphygmographic studies, to be of special value, should be continued in the same patients throughout an attack of mental disorder, and tracings finally obtained in convalescence should be preserved for comparison. Unfortunately, studies with the sphygmograph are laborious and time-consuming, but they are of such diagnostic and prognostic value in mental disorders that they have already become an indispensable part of alienistic science.—*Theo. H. Kellogg, M.D., Medical Superintendent of Willard State Hospital.*

Myxœdema Treated with Thyroid Extract.—At a meeting some months since of the Practitioners' Society of New York, Dr. Kinnicutt exhibited photographs and reported the condition of a myxœdematous patient, fourteen months after the beginning of treatment with thyroid extract. It had been found necessary to continue the treatment, and during the past eight months about twelve minims of a glycerine extract, representing less than a quarter in weight of the average single lobe of a sheep's gland, had been given every four days. The duration of the illness before the beginning of treatment had been twelve years, and the patient, on admission to the hospital, had exhibited the stage of advanced degeneration. There was marked general muscular paresis, the patient had been bedridden for a year, and there was distinct impairment of mental vigor. The great improvement after five months of treatment had been reported previously. With the continuance of treatment the health of the patient at the present date was excellent. The muscular power and mental condition were apparently normal, the patient was cheerful and able to attend to her simple daily duties. The hair on the scalp, from having been entirely lost, had continued to grow and at the present time was very abundant and reached to the shoulder. The probabilities seemed to be that it would be necessary to continue the treatment indefinitely, but that under these conditions good health would be maintained.

Electricity and Cats.—Our lay contemporary, the New York *Press*, has apparently joined the ranks of those papers which seriously propose to bring home to the minds of plain people the more important discoveries of modern medicine. The propriety of thus encroaching upon the proper territory of medical journalism is open to grave question. The public is so apt to draw wrong conclusions from even the most simplified presentation of erudite propositions, that the danger-point may be reached before suspicion has fairly been wakened. The electrical properties of cats are knowingly referred to in the *Press*. Evidently the writer was inspired by a profound respect for an article published recently in the *British Medical Journal*. The *Press* has this to say on the subject: In England the cat has just received her scientific vindication as a factor that makes for good in modern civilization. They have a National Cat Club in Great Britain, and at the recent annual meeting of this august body the secretary announced to an admiring audience of feline fanciers that cats, and more particularly old cats, were "intense." In family circles it has been known for some time that persons of recognized "intensity" were occasionally called "old cats." But a suspicion of slight opprobrium has generally been associated with this use of the term. The purely scientific correlation of intensity and cats is undeniably English, and likely to remain so for the present.

The "intensity" of cats, even of ordinary old toms, can be demonstrated by gently rubbing their backs in cold dry weather, and, preferably, in the dark. It will then easily appear that the animal is "full of electricity." It is therefore proposed to employ old cats as convenient storage batteries for electrical accumulation. It has already been accurately computed that a really intense cat, when properly charged, will give off enough electric sparks to shatter three ordinary attacks of hysterics. People subject to this distressing form of nervous disorder can now be seen in London accompanied by their intense cats. A stock company (limited) has also been organized, and is now in a position to supply certified felines of unimpeachable pedigree and requisite intensity for all functions where hysterics are apt to go off unexpectedly. Emotional first-nighters, girls who habitually get engaged and disengaged, æsthetic tea frequenters, Paderewski worshippers, grass widows, office seekers, and all individuals whose nervous systems require occasional fortification, now never venture out in London without a duly tested intense cat within easy reach. For children's parties and charitable enterprises kittens have been found strong enough. It is further proposed to use the "living feline galvanism" for curative purposes in cases where formerly the more complex and expensive system of hypnotic suggestion was in vogue. The *British Medical Journal*, in commenting on these interesting and epoch-making researches, says: "Apart from questions of electro-physiology, it is instructive to learn that the presence of white in the color of a cat, unless the animal be whole colored, is a sign of weakness. It is also interesting to know that the National Cat Club encourages the production of whole-colored cats and would in every instance have been successful in this, had it not been for the disappointing obstinacy of the tortoise-shell 'tom,' who, it appears, resolutely declines to become a cat of another color." On the whole, the cat seems as full of promising utility as of intensity. We congratulate the British National Cat Club on the eminent success of their feline labors. We await with bated breath the advent of "intense" cats in our country. Perhaps there are some here now. Who knows!

An Original Doctor.—There is a quaint and original doctor located on one of the islands on Puget Sound. He advertises in posters and placards printed in a home outfit. In one of his announcements he says: "Legs and arms sawed off while you wate without pane. Childbirth and tumors a specialty. No odds asked in measles, hooping cough, mumps or diarrear. Bald head, bunions, corns, warts, cancer and ingrowing tow nales treated scientifically. Coleck, cramps, costiveness, and worms nailed on sight. Wringworms, pole evil, shingles, moles, and cross eye cured in one treatment or no pay. Private diseases of man, woman or beast eradicated. P. S. Terms, Cash invariably in advance. No cure, no pay. P. S. (Take Notis.) No coroner never yet sot on the remanes of my customers, and enny one hiring me doan't haf to be good layin' up money to buy a gravessone. Come won, come awl.

This man is said to do a good business, although you would not expect it, and his patients say he cures diseases, and does it thoroughly and quickly."

Railway Sanitation.—Railroad companies are not allowed to carry the dead of infectious diseases except under certain conditions; why should they carry the living without any? It is the duty of national, provincial, and State sanitary associations to educate the people in matters of this kind. When educated, the people will demand protection, and when the people demand what is right and reasonable, corporations, which are said to have no souls, generally find it convenient and advisable to comply.—*National Board of Health Magazine.*

UMBILICAL HEMORRHAGE IN NEWLY BORN INFANTS.[1]

By CHARLES E. NAMMACK, M.D.,

VISITING PHYSICIAN TO GOUVERNEUR HOSPITAL, NEW YORK.

It is doubtful whether any disease having a correspondingly high mortality-rate has received so little attention as spontaneous bleeding from the navel in neonati. The infrequency of reported cases may account for this, as the issue is generally fatal, and cases with a fatal termination do not find their way into print with the same facility as do successful cases. It is probable that the death certificates of the fatal cases are filled out as hæmophilia; but the disease under consideration differs from hæmophilia in that it affects subjects much earlier in life than does the hemorrhagic diathesis, which seldom shows itself before the end of the first year. The blood in hæmophilia is usually coagulable, and not so in the disease here spoken of.[2]

Spontaneous umbilical hemorrhage is also a disease of a self-limited character, cases either going on to death or recovery within a few days,[3] whereas bleeders are apt to have a succession of hemorrhages from different points and extending over a longer period of time. Bovee[4] has collected all the cases in literature, from 1635 to 1891, to the number of five hundred and eighteen, and his article shows exhaustive study and research. He writes that the most prolific causes are hereditary diseases, such as syphilis and dyscrasiæ, either local or constitutional. Van Cott[5] thinks that there is overwhelming clinical evidence that jaundice exerts a profound influence toward producing the hemorrhagic condition, and says that of general causes syphilis should stand first and tuberculosis next, while of special conditions, absorption of sepsis at navel takes first rank.

The frequency of the disease in hospital practice, and its definite self-limited character, suggest its infectious nature, yet the records of eighty-one autopsies show nothing, in the majority of cases, except the hemorrhages and the resulting anæmia.[6]

C. F. Craig[7] says that the causes are: 1, A faulty condition of the blood; and 2, a pathologic condition of the vessel-wall, or a combination of both conditions. He quotes Sir J. Y. Simpson's opinion that syphilis causes thickening and infiltration, loss of contractility, and, therefore, a patulous condition of the vessel-walls.[8]

Albert Seppel[9] records an interesting case in which the cord fell on the seventh day, and hemorrhage, beginning on the eleventh day, proved fatal. Autopsy showed the right umbilical artery to be firmly closed, while through the left a fairly thick sound passed easily. Microscopical examination failed to disclose the reason for this disparity, as both vessels contained thrombi in various stages of organization, the thrombus in the right artery filling out entirely the lumen of the vessel, while that in the left artery left a space between the arterial walls. Bacteriological examination showed only the ordinary post-mortem microbes, no specific agent being found.

Klebs and Eppinger[10] have described a micrococcus found in this malady, which they called monas hæmorrhagicum.

Dr. Lefour[11] gives the history of a family of five children. The first two died from umbilical hemorrhage. The cord of the second was examined microscopically, and endarteritis was found. The third and fourth children were raised without accident. The fifth child was born at term, and the cord tied with a caoutchouc thread. On the fourth day hemorrhage occurred and was controlled by ligature *en masse*.

Dr. P. Lugeal[1] reports five cases, which do not throw any light on either the etiology or the pathology of the condition.

Helen F. Warner[2] publishes three cases, of which two recovered.

J. Taylor[3] narrates three cases in the same family, the first two of which were fatal. The third recovered under the local use of a solution of one ounce tannin in one ounce rectified spirits. Taylor thinks it would be worth while to give chloride of calcium by the mouth in these cases. This therapeutic possibility has been recently spoken of by W. Gilman Thompson.[4] The symptomatology of this disease is typically illustrated by the narration of the following case:

Sarah L——, aged four days, was sent to Gouverneur Hospital, March 1, 1895, with the following history: She is the sixth child. The other five were still-born prematurely on account of syphilis in the mother. During the sixth pregnancy the mother received constantly anti-syphilitic treatment, and was delivered at term by a midwife, without any difficulty, of an apparently healthy child. On the third day jaundice developed, and on the fourth day the cord became detached spontaneously. Shortly after, hemorrhage from the navel began and was checked by styptic cotton and a bandage. It soon recurred, and the child was taken to a dispensary, where a plaster bandage was applied. This checked the bleeding for a brief time only, and on its reappearance the baby was brought to the hospital. On admission she was markedly jaundiced and profoundly anæmic. The bleeding resisted attempts at compression, and the visiting surgeon, Dr. Henry M. Silver, applied a purse-string suture which checked the oozing for several hours. It came on again, however, and the child died on the sixth day after birth, and twenty-four hours after admission to the hospital.

Regarding the pathology of the affection it will be seen that there is a decided lack of unanimity on the part of writers, and it is probable that widely different pathological causes may give rise to the condition. The "American Text-book of the Diseases of Children," p. 86, says that "in cases where syphilis, hæmophilia, septic infection, and acute fatty degeneration with hæmoglobinuria, are present, hemorrhage may occur when the cord separates, or even before that time."

Hæmophilia, as a causative factor, may be excluded for the reasons already given. Septic infection may reasonably be expected to present a different clinical history from that which obtains in typical cases of spontaneous umbilical hemorrhage. Acute fatty degeneration has been made the subject of careful study by Dr. Mary Putnam-Jacobi,[5] and Partridge[6] seems inclined to accept this condition as the essential cause. In the hope of adding something to our knowledge of the pathology of the affection, the coroner's consent to the removal of some of the organs in the writer's case was obtained, and Dr. F. Ferguson, pathologist to the New York Hospital, kindly undertook their examination and has furnished the following report:

The material consists of the heart, lungs, liver, kidneys, stomach, and portion of intestines. Also the integument surrounding the umbilicus with the umbilical vessels attached. The heart and blood-vessels appear normal. There are a few hemorrhages in the lungs and liver. Otherwise all the organs appear normal. There is an opening at the site of the umbilicus, dark in color,

and 1 ctm. in diameter. A probe, ½ ctm. in diameter, passes freely through the opening up to the liver.

Microscopical examination was as follows: Transverse sections of the cord at different levels show the umbilical arteries contracted and apparently normal. The cord is extensively infiltrated with small round cells which form areas of considerable extent and are very rich in vascular supply. Those small vessels vary greatly in the thickness of their walls and all of them are intensely hyperæmic. Many of them are surrounded by hemorrhages which are of considerable extent. The hemorrhages are seen to be more abundant and extensive as the sections approach the union of the cord with the integument. In some of the sections only a few vessels are observed, but the hemorrhages into the tissues are most extensive. None of the sections made shows the vessels to be the seat of thrombi. The wall of the umbilical vein is not well defined, and the vessel is surrounded by small round cells which are closely packed together. The hemorrhages in the cord are the result of defective small vessels, and the larger hemorrhages come from the umbilical arteries, neither of which is found occluded. Examinations of the vessels of other organs reveal no lesion, but there are hemorrhages of minute sizes in the spleen and kidneys. The cells of the liver refuse very generally the hæmatoxyline stain, and vast numbers of streptococci are found in the liver, spleen, and kidneys. These are seen between and within the tubules in the kidneys, and in the liver within the vessels, on the surface of the cells, and in the stroma.

From the pathologist's report it would seem that the essential cause of the hemorrhages in this case was a degeneration of the walls of the vessels, and from the clinical history the conclusion is inevitable that syphilis caused the degeneration.

J. Collins Warren[1] adopts the opinion that the umbilical arteries are closed by a growth which takes place from the intima, by which the calibre of the vessel is narrowed, and that new walls are thus formed within the old, the complete closure of the vessel depending upon a proliferation of endothelial cells rather than upon a thrombus. Further on he states (p. 136) that Thoma's assumption that a portion of the newly found tissue is of a muscular character is fully confirmed.

Tight Lacing and Gall-stones.—Professor Marchand, of Marburg, has again called attention to the fact that gall-stones and tight lacing are frequent coincidents. The furrow caused by lacing runs directly across the right lobe of the liver, causing a tendency to atrophy of the gall-bladder. When tight lacing has been extreme, an artificial fissure is formed in the liver, giving rise to what is termed the "lacing lobe," which carries with it the gall bladder. Stagnation of the bile is well known to be one of the most important causes of the formation of gall-stones. A change in the composition of the bile, from catarrh resulting from congestion of the mucous membrane and the thickening of the bile due to failure of the gall-bladder to completely evacuate itself, gives rise to the formation of small masses which serve as nuclei for calculi; hence, anything which obstructs the free outflow of bile through the cystic duct must favor the formation of gall-stones. Marchand is also of the opinion that many cases of cancer of the liver should be attributed to tight lacing. It is only a few years since a German surgeon was obliged to open an abdomen to remove a "lacing lobe" of the liver, which had been so completely separated from the rest of the organ as to cause its death, rendering its removal necessary.—*Modern Medicine.*

In 1781 Ramdohr first successfully united the human bowel by suture, after complete division.

A CLINICAL STUDY OF CASES OF PERSISTENT ABSENCE OF THE GASTRIC SECRETORY FUNCTION.[1]

By D. D. STEWART, M.D.,

PHILADELPHIA, PA.

LECTURER ON MEDICINE IN THE JEFFERSON MEDICAL COLLEGE.

GRATITUDE is due to Leube for the introduction of modern methods of research that have made a diagnosis of atrophy of the gastric tubules possible, and to Javorski, whose method of stimulating the indolent secretory follicles in cases of fictitious atrophy has allowed of the certain diagnosis of arrested secretory function, although it does not at once permit the pathological diagnosis, that of atrophy. This last and the separation of curable cases of neurosal inhibition from those of true atrophy can be made clinically with great positiveness after a time. This separation is arrived at by the long and steady duration of the secretory loss and total lack of response to treatment to provoke return, in face of complete restoration to function of the coincident disturbed motility—the actual cause of most of the symptoms, direct and remote, of the affection. The separation from latent gastric carcinoma, especially from the infiltrating form, is made by the absence of cachexia, of wasting, by the duration of the case, and if atony prevail, as is common, by the presence of marked and persistent lactic-acid production. In gastric carcinoma, save in its terminal stage, as also in chronic gastritis, although free HCl is absent, and the gastric secretion after a trial-meal shows no digestive activity, a fair amount of pepsin and rennin may be readily extracted from the tubules by Javorski's method, unlike what is the case in primary atrophy of the tubules. These ferments have existed in the formative or potential stage as proenzymes, and needed but the stimulating influence of HCl, under certain favorable conditions, for their conversion into active digestants easily recognizable. In these cases of carcinoma, and in cases of chronic gastritis where there is doubt as to diagnosis, it is shown that the amount of acidity, the presence of indications of bound HCl, and of certain fermentative changes in the filtrate, greatly assist in diagnosis from atrophy, as do also the appearance in the wash-water of shreds of mucous membrane and always of epithelial cells; these, and in cancer sometimes cell-nests or small pieces of the growth, assist in the exclusion of atrophy of the gastric tubules, especially as a primary affection. The acidity of the removed contents in cases of primary arrest of gastric secretion is always very low, and consists, save in exceptional instances, only of that of the food eaten, as I have shown by experiment.

The cases here described are of especial interest, occurring as they do as an idiopathic affection, unlike many cases described by Reichmann, Javorski, and many others, in which there was often antecedent history of chronic gastritis or the presence of carcinoma.

I have followed these cases for several years; two for nearly three years; the other for over four years. One, the most instructive, first came under observation with symptoms of chronic arthritis, due to the deposit of urates in the joints, as was shown by the presence of certain symptoms and a careful study of the urine over a long period. She was an invalid—chair-ridden. Gastric symptoms were practically absent. Symptoms of renal fibrosis were evident, and were regarded as in the early stage. Marked atony of the stomach existed, and, as in all the cases I describe, total and continuous absence of secretion of gastric juice—of HCl, of pepsin, and of the milk-curdling ferment.

The second case presented herself for treatment with symptoms of grave anæmia, which had recurred in at-

[1] Abstract of a paper read before the College of Physicians of Philadelphia, April, 1895.

tacks of months in duration for several years. With these symptoms were those indicative of the condition described by our President as cardiac asthenia. Gastric symptoms were in the background. Neither of these cases showed the slightest indication of a neurosis. One is in middle life; the second is thirty-five years of age. The third case, also a woman, thirty-three years of age, is a typical neurotic. In this case more doubt has all along existed as to the condition underlying the absent secretory function. I feel that I may now say concerning it that, although its origin may be regarded as neurosal, its long and steady continuance over an observed period of four years is very suggestive of atrophy of the tubules.

In the first two of the cases a complete removal of all symptoms occurred under treatment directed to re-establishing secretion, in all probability through it equally influencing the impaired motility. The treatment consisted chiefly in the use of the hot stomach douche, intra-gastric electricity, and of large doses of HCl. In the other cases the douches and intra-gastric electricity could not be employed. In the second the free use of HCl and intestinal disinfectants seemed mainly the cause of the improvement. Both of these two cases have been in perfect health for over a year, have gained largely in weight (both weigh more now than ever before), and eat and digest without discomfort, like ordinary normal individuals, although no secretion of gastric juice ever occurs. Digestion, of course, goes on in the bowels by the aid of the pancreatic secretion. It is here pointed out that the conduct of these and similar cases clearly establishes the truth of Bernard's belief that the stomach, even under the most favorable conditions, can be regarded as little more than a reservoir for food and as a conduit to the duodenum, where perfect digestion occurs. They certainly prove that the secretory function is secondary in importance to that of motility. Recent experiments of Kuhne and Chittenden have shown that even under the most favorable circumstances true peptonization occurs only to a limited extent in the stomach, and that gastric digestion is but a preliminary stage to more perfect intestinal proteolysis. But on account of the almost certain likelihood in the great majority of cases of absent gastric secretion, as in other affections of the stomach characterized by mere diminution of the same, of coincident involvement of motility, thus originating atony and its train of ills, loss of secretory function must be viewed with great gravity. Hence Meyer believes that these cases, whether secondary or idiopathic, rarely last more than a few months to two or three years.

The third of my cases is a chlorotic woman, in whom a decided neurotic element has rendered her less susceptible to general improvement. She had had epileptoid seizures for several years before she came under observation. She would submit to the tube only for diagnostic purposes, and even then with reluctance, its employment often causing an hysteroidal seizure. The douche and the use of intra-gastric electricity could not be employed for these reasons. Her nutrition is now always fair, and at times very good. Gastric symptoms of the sort described by Boas and others did not occur at all in Case I. and were slight in Case II. Case III. had the characteristic vomiting and pain after meals. These were removed by the free employment of HCl, and do not recur on its continuance. She has voluntarily continued it quite steadily in large doses for four years.

In none of the three is there gastrectasia, a symptom regarded as common by Meyer and others.

In the first and second cases the origin of the secretory loss is most obscure; in the third a neurotic element is so prominent that it may be regarded as the source of the disorder. In the others none exists. In origin all of these cases may have been those of neurosal suppression of secretion — inhibition arising through some long-continued reflex irritation not now evident. Whatever the primary determining cause may have been, the long duration of the affection, with perfect restoration of motility, in the face, in two, of complete, and thus far permanent restoration to health, renders the continued absence of gastric secretion of great significance and grave omen. For because of the functions of secretion and motility being, as they are, so intimately connected by innervation through the vagus and sympathetic, it is reasonable to suppose that complete restoration of impaired nerve functioning in one, as in restored motility, would, after so long a time in which restoration has continued, lead to at least partial return of secretory power. This should especially be were the trouble merely functional, when treatment as successful in restoring secretion in other gastric affections has here been long tried resultlessly. These cases in origin may have been, through causes not apparent in at least two, those of neurosal suppression of secretion, and have arisen through long-continued reflected disturbance in gastric innervation, impairing jointly motility and secretion. I regard in this particular a suggestion of Stockton's as especially worthy of attention. He asks if we may not have to do here with an affection which at the start is functional merely, but the long-continued inhibition of glands is succeeded by atrophy. This had been my own thought, although I am unable to accept his evident preference for eye-strain as the source of reflected irritation. In every case observed by him, curiously, a very similar condition of high refractive error existed in all—unsymmetrical astigmatism of high degree, varying from 1 to 5 D. There also was noted, in all, irregular ametropia, myopia in one eye, hyperopia in the other, with a lack of correspondence in the axes of astigmatism. It is interesting that the one case (the neurotic) in which such errors would be more operative has practically no eye-strain. Apart from a low hyperopia the eyes were quite normal. In Case I. some refractive error existed, but not of the pronounced character noted in Stockton's cases. She is a woman of strong will and sound nervous organization, one little likely to be affected by such a reflected condition as is present. In Case II. less refractive error was found than in Case I.—too slight error, according to Dr. Gould, to cause any serious reflex. Inquiry of Dr. Einhorn as to the condition of refraction in his four cases elicited the response that no refractive trouble was found to exist in two of the four A third is crossed-eye. No examination had yet been made in the fourth at the date of Dr. Einhorn's letter.

As concerns therapy, it is practically useless, after long trial to hope to restore secretory activity, although, since the same remedies are applicable to maintain the motor function, they may be resorted to for periods of a few weeks or months from time to time. The remedies most useful are those influencing motility, obviating stagnation, and maintaining good motor power when re-established. The chief of these remedies, incomparably superior to all others, is the intra-gastric use of electricity, contrasted with which drugs, such as strychnine, are as nothing. As the use of HCl, which favors secretory return, seems also to influence the impaired motility, it may also be employed. HCl is more especially indicated when the case first comes under observation and doubt exists as to the pathological condition underlying the absent secretory function. It should then be used for months at a time. It must be employed in rather large doses, such as from 4 to 8 c.c. (℥j. to ℥ij.) of the dilute acid, and for best effect as a secretory stimulant should be given before meals. I give it in this amount in decinormal solution (0.364 per cent. absolute HCl), preferably introducing it through a soft stomach-tube, which the patient enters to the first part of the œsophagus. Even in one unaccustomed to the tube and prejudiced to its employment, so little discomfort after a trial or two is experienced by its introduction only thus far, especially if cocaine is first

used for a few times, that it is in nearly all cases willingly resorted to. Thus is avoided the disagreeable taste and the effects upon the teeth of the large volume of acid necessary in these cases.

Artificial digestants are rarely required in these cases. What is essential is attention to the motor function. If for any reason digestion is regarded as imperfect in the bowel, through coincident failure of pancreative secretion, certain digestive agents are of use for a time. Should failure of a good digestive secretion on the part of the pancreas be permanent, nothing then can, of course, hope to avail for more than a short time. The administration of HCl or of HCl and pepsin as digestants, for obvious reasons, fully considered, are utterly unphysiological. HCl alone can, of course, be of no utility, unlike the case in gastric catarrh or in simple nervous depression of secretion. Secretion of pepsin cannot be hoped to be stimulated by it from glands long the seat of atrophy. With pepsin it is also inutile, as sufficient cannot conveniently be constantly taken to completely saturate the albuminoids and salts of the food after a moderately large meal. To support this may be cited the interesting experiments of Blum (recently quoted by Chittenden in his Cartwright lectures), who shows that with a daily consumption of 100 grammes of proteid, a fair average, there would be required no less that 4½ litres of 0.2 per cent. of HCl daily, and even this would not suffice to give free acid. The only physiological digestant in these cases is a pancreatic preparation, or one of the vegetable digestants, papain or pineapple juice.

THE CURATIVE VALUE OF THE ANTITOXIN.[1]

By I. P. KLINGENSMITH, M.D., F.S.Sc.,

BLAIRSVILLE, PA.

SURGEON PENNSYLVANIA RAILROAD; EX-PRESIDENT WESTMORELAND COUNTY (PA.) MEDICAL SOCIETY; MEMBER AND EX-PRESIDENT INDIANA COUNTY (PA.) MEDICAL SOCIETY; MEMBER MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA; OF THE AMERICAN MEDICAL ASSOCIATION; OF THE BRITISH MEDICAL ASSOCIATION; OF THE NATIONAL ASSOCIATION OF RAILWAY SURGEONS; OF THE PITTSBURG OBSTETRICAL SOCIETY; FELLOW OF THE MEDICO-LEGAL SOCIETY OF NEW YORK; CORRESPONDING MEMBER NEW YORK ACADEMY OF ANTHROPOLOGY; FELLOW OF THE SOCIETY OF SCIENCE, LETTERS, AND ART OF LONDON, ETC.

During the past century innumerable agents have been employed in the treatment of infectious diseases with varying degrees of success. When the microorganismal nature of the infectious diseases was established the antiseptics were brought into use. Their action outside the body, however, is no criterion of their action when introduced into the body, as experience has clearly shown that it is useless to aim at disinfection within the body. Through bacteriological research the situation has changed, and we have every reason to believe that for the various specific diseases specific remedies may be found. Science has at last triumphed and given to the world the long sought for specific for diphtheria in the antitoxin serum. Behring, of Berlin, began his experiments with this new therapeutic agent in 1890, and in August, 1891, read a paper at London before the Seventh International Congress of Hygiene and Demography, in which he detailed his methods and results. Roux, of Paris, after pursuing a series of experiments in the treatment of diphtheria by the antitoxin serum, since 1891, and thereby having obtained a sufficient number of facts to enable him to judge the method properly, read a "Contribution to the Study of Serum Therapy in Diphtheria" before the Eighth International Congress of Hygiene and Demography, held at Buda-Pesth in September, 1894. In this paper M. Roux sets forth that his results fully confirm in all essential points those that have been published by Behring and his collaborators.

The Technique.—As this method of treating diphtheria is about to become general, I will briefly refer to the technique of the operation. Of primary importance is the selection of a reliable preparation of the serum. Having had personal experience in the administration of both American and German solutions, the results obtained justify me in giving the preference to the former. The home product has in my hands proven itself to be of greater efficiency, and can be obtained in a much fresher state. Antitoxin serum being administered hypodermically, it is therefore necessary to use a suitable syringe. As the required dose should be administered at one injection, the ordinary hypodermic syringe, on account of its limited capacity and the small calibre of its needles, will not answer the purpose. My first experience was with a Pasteur syringe. This I found unsatisfactory on account of its having leather fittings, which make it almost impossible to sterilize and render aseptic, and frequently dry out in such a manner as to make the syringe useless. The syringe now used by me was devised by Dr. Louis Fischer, of the New York Post-Graduate Medical School, and is made by George Ermold, No. 312 East 22d Street, New York. It consists of a glass barrel like any ordinary aspirating syringe, with asbestos fittings, and has a capacity of 15 c.c. The calibre of the needles is large, owing to the thick consistency of the serum. This syringe is entirely aseptic and can be sterilized without being taken apart, and its asbestos packing can be properly regulated by screwing the ring handle to tighten or loosen the packing. The technique of injection is simple. It should be borne in mind that the serum being aseptic, the entire operation must be conducted under the strictest antiseptic precautions, just the same as though we were performing any important surgical operation. I now properly sterilize the syringe by boiling and using 0.1 per cent. solution of lysol. On account of it being necessary to inject so large an amount of the serum, the locality selected should be one over which the skin is quite free. The region preferred by me being in the intra-scapular space. The serum should be injected slowly, the puncture sealed with cotton and five per cent. iodoformized collodion. The injections are almost painless and massage is unnecessary, as the swelling caused by the fluid disappears quickly. The following six cases of diphtheria came under my observation, during the past winter and spring. These were treated by antitoxin, and the results were so uniformly favorable that I feel it my duty to report them, thus adding my small tribute to one of the greatest discoveries of the nineteenth century.

Case I.—Child, female, aged 5; occurred in the practice of Dr. A. T. Rutledge, of Blairsville, and was seen by me in consultation, January 26, 1895. For the appended notes on the cases given below I hereby acknowledge my indebtedness to the attending physician. First visit, January 24, 1895, when I found a well-defined case of diphtheria on fifth day of disease; temperature, 102° F.; pulse, 120; the tonsils and uvula being covered with diphtheritic membrane, submaxillary glands enlarged and tender, characteristic odor well marked, child suffering from prostration and very dull and listless. At once informed the family that their child was suffering from diphtheria. Prescribed the usual remedies until 2 P.M. January 26th, when the case was seen in consultation by Dr. I. P. Klingensmith. As at that time the general septic condition of the patient was so manifest, we looked upon the case not only as hopeless for recovery, but questioned the propriety of administering the antitoxin, not desiring to bring the remedy into disrepute in the event of failure. But notwithstanding this unfavorable outlook, we administered 15 c.c. Gibier's antitoxin. This was followed, at 6 A.M. on the 27th, with 10 c.c.; February 5th, 10 c.c.; February 8th, 10 c.c.; and on February 12th, 5 c.c. On making my visit at 6 o'clock on the morning of the 27th, sixteen hours after the administration

[1] Read before the Indiana County (Pa.) Medical Society, May 13, 1895.

of the first dose of antitoxin, I found marked improvement of the patient, general and local symptoms were more favorable, temperature lower and pulse stronger. The child passed through a gradual and uneventful convalescence to a complete recovery.

Case II.—Iola T——, aged two years and nine months. Saw this case March 8, 1895. This patient presented all the clinical manifestations of the malignant type of diphtheria. Pulse, 140; temperature, 103° F. My supply of antitoxin at the time being limited to 3.5 c.c. Gibier's antitoxin, at 11 P.M. administered the same.

March 9th, 9 A.M.: Pulse, 130; temperature, 102.5° F. No improvement, except that the small dose of antitoxin administered the previous night stayed the further progress of the disease.

March 9th, 7 P.M.: Pulse, 135; temperature, 102.5° F. Administered 4 c.c. Behring's serum No. 3. March 10th, 10 A.M.: Pulse, 130; temperature, 101° F. Administered 4 c.c. Behring's serum No. 3. March 10th, 5 P.M.: Pulse, 135; temperature, 100.5° F. March 11th, 10 A.M.: Pulse, 100; temperature, 99° F. After the administration of the second dose the child made a rapid recovery.

Case III.—Ida M——, aged twenty-one. Was called to see this patient at 10 P.M., March 9th: Pulse, 140; temperature, 103° F.; general constitutional disturbance. Diphtheria suspected in consequence of having been exposed in a case which resulted fatally.

March 10th, 12 M.: Disease well developed, tonsils covered with exudation, submaxillary enlargement, and characteristic odor of diphtheria. March 10th, 3.30 P.M.: Pulse, 140; temperature, 103° F.; 15 c.c. Gibier's antitoxin. March 10th, 9 P.M.: Pulse, 140; temperature, 103.5° F. March 11th, 9 A.M.: Pulse, 110; temperature, 101.8° F.; 10 c.c. Gibier's antitoxin. March 11th, 4 P.M.: Pulse, 100; temperature, 102° F. March 12th, 9 A.M.: Pulse, 96; temperature, 99° F. March 12th, 4.45 P.M.: Pulse, 98; temperature, 99° F. March 13th, 10.15 A.M.: Pulse 84; temperature 99° F. March 13th, 4.10 P.M.: Pulse, 90; temperature 98° F. March 14th, 9.50 A.M.: Pulse, 98; temperature, 98.5° F. March 14th, 5.20 P.M.: Pulse, 90; temperature, 98.5° F.

Two days later found no further visits indicated, as patient was practically convalescent. On March 10th administered immunizing dose, 3 c.c. Gibier's antitoxin, to each of five other members of that family, none of whom contracted the disease.

Case IV.—Female, aged twenty-seven. This case first came under my observation March 8th, and from the history given, elicited the information that she had been sick since February 15th, when an attack of tonsillitis resulting in suppuration was followed by laryngitis, which by February 26th had rendered her unable to speak beyond a whisper.

When I first saw this case on the evening of March 8th, she was suffering from subacute laryngitis, and unable to speak except in aspirates, very rapid pulse, and patient suffering from prostration to an extreme degree. Upon inspection, found redness of the fauces, with slight submaxillary tenderness.

March 9th: Small patch of exudation on right tonsil, submaxillary glands enlarged and more tender. March 10th, 4.45 P.M.: Pulse, 130; temperature, 99.5° F. Exudation on both tonsils, submaxillary glands more tender.

March 10th, 4.45 P.M.: Pulse, 130; temperature, 99.5° F. Exudation on both tonsils, submaxillary glands more tender and much enlarged. Administered 15 c.c. Gibier's antitoxin. March 11th, 10 A.M.: Pulse, 110; temperature, 100° F. Administered 4 c.c. Behring's serum No. 2. March 11th, 5 P.M.; Pulse, 120; temperature, 101.5° F. March 12th, 10 A.M.: Pulse, 120; temperature, 102° F. Administered 8 c.c. Behring's serum No. 2: March 12th, 5 P.M.: Pulse, 110; temperature, 101° F. March 13th, 10.30 A.M.: Pulse, 110; temperature, 99.5° F. March 13th, 4.30 P.M.: Pulse, 110; temperature, 99.5° F. Some diphtheritic exudation still existing, I administered a final dose of 15 c.c. Gibier's antitoxin. From this on the convalescence was uneventful, resulting in complete recovery.

Case V.—Jennie W——, aged nineteen. March 12th, 4.30 P.M.: On third day of the disease, pulse, 120; temperature, 104° F.; both tonsils completely covered with heavy diphtheritic exudation, very extensive submaxillary enlargement, and, in fact, presenting all the clinical manifestations of a case of diphtheria of a very grave type. In the presence of Dr. L. S. Clagett, of Blairsville, administered 15 c.c. Gibier's antitoxin. March 13th, 11.15 A.M: Pulse, 90; temperature, 99.5° F. Diminution of submaxillary enlargement, no further extension of exudate, and improvement of general condition of patient. Administered 10 c.c. Gibier's antitoxin. March 14th, 9.30 A.M.: Pulse, 78; temperature, 98° F. March 15th, 9.20 A.M.: Pulse, 78; temperature, 98° F. March 16th, 9.40 A.M.: Pulse, 72; temperature, 98.5° F. Throat free from membrane, very rapid convalescence to complete recovery.

Case VI.—Earl R——, aged six. March 18th, 3 P.M.: Saw this case in consultation with Dr. E. W. Blackburn, of Latrobe, Pa. Both tonsils were covered with a thick exudate with an offensive odor. Disease had progressed for three days. Pulse, 100; temperature, 99° F. Administered 15 c.c. Gibier's antitoxin. 6 P.M.: Pulse, 108; temperature, 100.5° F. March 19th, 8.30 A.M.: Pulse, 90; temperature, 99.5° F. 6.30 P.M.: Pulse, 100; temperature, 100° F. General improvement. Administered 10 c.c. Gibier's antitoxin. March 20th, 10 A.M.: Pulse, 84; temperature, 99° F. 6 P.M.: Pulse, 96; temperature, 99.5° F. March 21st, 9 A.M.: Pulse, 88; temperature, 99° F. 6 P.M.: Pulse, 84; temperature, 98° F.

Throat entirely free from membrane, pulse and temperature remaining normal, child made rapid recovery. For the above notes my thanks are due to the attending physician.

In Cases I. and II. no local treatment was carried out; in the other cases Seiler's solution, or a solution of peroxide of hydrogen, was used to assist in removing the membranes as they became detached. Stimulants should be used freely in all cases. In a family in which a case of diphtheria occurs, the other members should be at once immunized. It is needless to say that these cases are not selected mainly for publication, but are such as presented themselves consecutively in practice. It should be here remarked that the infection propagating the disease in Cases II., III., IV., and V., emanated from the same source, viz., from the case of a child who died in the family where Cases II. and III. followed. From my experience in the management of the above six cases, I feel perfectly free to say that antitoxin is a safe remedy, and therefore in any case presenting the clinical manifestations of the disease I would be willing to err by giving too much rather than too little of the serum. In the months of September, October, and November, 1891, during the prevalence of the disease at Blairsville at that time, I treated thirteen cases, with eight deaths and five recoveries, making a mortality of about sixty-two per cent. These cases were treated by the most approved methods then known to the medical profession.

These eight cases, which in 1891 resulted fatally, presented no greater degree of malignancy than Cases I., II., III., and V., that were recently treated with antitoxin and progressed to rapid and complete recovery. At the Congress of Internal Medicine recently held at Munich, Huebner communicated new statistics regarding the effects of the antitoxin treatment of diphtheria. In a total of three thousand cases collected from different parts of the world, the mortality was twenty per cent. Baginsky reported that at the Kaiserin Hospital the mortality, which used to range about forty per cent., has been reduced to thirteen per cent. Ranke, of Munich, found that under serum

therapy the mortality-rate fell from forty-two per cent. to 18.6 per cent. Statistics of the Paris hospitals show that the death-rate of diphtheria has decreased from sixty per cent. to twelve per cent. In the face of this record of the wonderful decrease in the mortality-rate of this dreaded disease, it seems to require no prophetic power to foresee that we are on the threshold of discoveries in medicine such as will eclipse all that have preceded them.

Progress of Medical Science.

A Modification of the Invagination Method of Operating for the Radical Cure of Hernia.—At a recent meeting of the Philadelphia Academy of Surgery, Dr. John H. Packard detailed a method of operating for the radical cure of hernia, which consists essentially in the invagination of the isolated sac (*Medical News*). The hernia is exposed by a curved incision describing a semicircular flap of ample size. In this manner the cicatrix is carried away from the seat of trouble, which is afterward covered in by sound skin. The sac is laid bare and isolated from the external ring down to its tip. Sometimes it is better to empty it during this process, which may often be accomplished by tearing with the fingers. It is well to begin the isolation at the ring and to proceed downward. In order to secure control of the empty sac a silk thread is now passed through its wall at either side ; the two ends of each are left long and caught in hæmostatic forceps. With the forefinger of the left hand the tip of the sac is inverted and pushed up as far as the internal ring, or as near it as possible. Next, a slightly curved needle, with an eye near the point, and armed with a thoroughly sterilized silk thread, is passed up along the finger as a guide, to be pushed out at one side of the tip through the tendon of the external oblique muscle. One end of the thread being caught, the needle is withdrawn slightly, and again pushed through the tendon at the other side of the tip. The other end of the silk thread is now detached from the needle, which is wholly withdrawn, and the two ends left slack are caught together in a hæmostatic forceps. Now, by means of the two lateral threads, and by grasping in the fingers, the doubled sac is drawn down carefully, and with a small curved needle a fine silk suture is passed through it from side to side, from below upward as far as possible, and then from above downward, so that its two ends, when drawn tight, will crumple up the sac into a solid mass. These ends are tied and cut off short. The lateral threads are now removed, and the other silk thread is drawn up tight, pulling the plug formed of the sac into place at the internal ring ; its two ends are tied on the outer surface of the tendon of the external oblique and cut off short. The skin-flap is laid over in place again, the wound closed by sutures, and the ordinary antiseptic dressings applied. The patient is kept in bed until the wound is completely healed.

The Blood in Chronic Cyanosis.—In studying the blood of eight cases of chronic cyanosis from congenital heart-disease, Dr. Vacquez found marked changes. In all cases the number of red corpuscles per cubic millimetre was increased, the increase being in direct ratio to the intensity of the cyanosis. Besides the increase in the number of the red corpuscles, an increase in size was also noted, though not until the cyanosis had become quite marked ; in fact, in the earlier years of cyanosis the increase in number was only relative. In individuals of from twelve to twenty years of age blood-counts of from 5,600,000 to 6,300,000 were found, the diameter of the corpuscles varying from 7.9μ to 12μ. Vacquez does not think that the increase in number of the corpuscles was parallel to the increase in diameter, but thinks that both are due to the same cause. At the same time with the increase in size and number of the corpuscles, there is an increase in the amount of hæmoglobin in each individual corpuscle, so that the hæmoglobin does not show its normal relation to the number of corpuscles. The question as to whether the increase in size of the corpuscle or the increase in hæmoglobin is the primary process cannot well be answered. The process has been explained on the grounds that in cyanosis the supply of oxygen carried to the tissues is insufficient, and that the corpuscular new-formation is compensatory. Gibson, in *The Lancet*, reports a case of a boy, aged eight years, whose red blood-corpuscles were 8,470,000 per c.c., and the hæmoglobin one hundred and ten per cent. He refers to other instances in which this increase in the blood-corpuscles has been noted, and suggests the following interesting explanation : "In venous stasis the corpuscles are insufficiently oxygenated ; they cannot perform such an active part as oxygen-carriers, and they cannot yield too much oxygen to the tissues. It must further be remembered that in cyanosis there is less metabolism in the tissues, and therefore less waste produced. In a word, the functions of the corpuscles being lessened, the tear and wear which they undergo are reduced and the duration of their individual existence increased. The number of the corpuscles must in this way be proportionately augmented, and this must lead to the numerical increase as well as to the high percentage of hæmoglobin, until a balance is struck between the production and the destruction of the blood-corpuscles.—*The American Journal of the Medical Sciences.*

Nucleated Red Corpuscles in the Blood.—Zenoni says that Bizzozero, Rieder, and others have noticed the appearance of nucleated red corpuscles in the blood after considerable or repeated hemorrhage. These corpuscles were usually noticed some days only after the occurrence of the hemorrhage, but Zenoni, in consequence of his experiments, places their appearance much earlier (*The British Medical Journal*). His experiments were made on dogs, guinea-pigs, and rabbits, in whose blood he had previously satisfied himself that there were no circulating nucleated red blood corpuscles. He chose a dog weighing 6,700 kilog., and in ten repeated operations withdrew from it a total of 1,830 c.c. of its blood ; then, after defibrinating the blood, he reinjected it into the circulation, and in an hour and a half after the operation noticed the appearance of nucleated red corpuscles in the circulating blood on examining a specimen under the microscope. In two other dogs similarly treated the appearances of these corpuscles in the circulating blood took place five hours and a half and seven hours and a half after the operation. In another dog, two rabbits, and four guinea-pigs, in whom a moderate amount of blood was withdrawn at a single operation, the appearance of nucleated red corpuscles occurred between eighteen and forty-eight hours after the operation. Zenoni thinks that the rapid appearance of these corpuscles is due to the mechanical effect produced by the withdrawal of blood, for after repeated bleedings they appear too soon for their reappearance to be due to a hæmatopoietic reaction ; moreover, eight or nine days afterward they are no longer noticed, exactly when the hæmatopoietic reaction is at its maximum. He further thinks that after loss of blood these corpuscles are mechanically drawn into the circulation from their normal site, the bone marrow ; that a certain number of them get stopped in the spleen, proliferate there, and give to the spleen that fœtal hæmatopoietic function which has been ascribed to it by Bizzozero as taking place after hemorrhages.

A Medical Witness in a Tacoma court, being asked whether medicine was an art or a science, replied with a sigh that it was neither one nor the other, but as yet merely an experiment.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 10, 1895.

THE CAUSE AND TREATMENT OF FLATULENCE.

IN an article in the *Practitioner* for July, 1895, Dr. Stephen McKenzie gives a very interesting and practical discussion on the subject of the treatment of flatulence. There are, he says, probably few diseases which, without being of a serious nature, give rise to such discomfort as flatulence. The usual story is that soon after a meal, or, perhaps, quite independent of the partaking of food, there is a feeling of fulness at the epigastrium. The patient loosens the waist-band, and all constricting garments; there is a painful sense of oppression, a difficulty in breathing, perhaps palpitation of the heart, and, not infrequently, flushing of the face, with cold hands and feet. An actual vertigo may occur, and, if the patient is of a nervous temperament, he or she may become almost hysterical, or, at least, go into a state of profound nervous depression and alarm. After a time the cardia relaxes, some gas escapes, and rapid relief occurs.

Dr. McKenzie discusses the causes of this flatulence. A certain amount of air, he says, is swallowed in the process of mastication and deglutition; but he does not consider that this swallowed air ever produces any of the phenomena associated with flatulence. The second and the common cause to which flatulence is attributed is fermentation occurring in the food in the stomach. Dr. McKenzie does not believe, however, that the gas of flatulence is the result of food fermentation. He cites the experiments of Sir William Roberts, who shows that fermentative processes are too slow for the rapid development of flatulence in dyspepsia, and shows further that the gas which results from fermentation can only develop when food is retained in the stomach for from twenty-four to forty-eight hours. The use of anti-zymotics, which is so popular for fermentative dyspepsia, and which undoubtedly has a beneficial effect, cannot act by stopping the fermentation of food, since, as Dr. McGuire has shown, the amount of creosote and other antiseptics given is quite insufficient to stop putrefactive changes. The fermentation theory of flatulent dyspepsia must, therefore, be dismissed.

Sir William Roberts has shown that a certain amount of flatulence may occur in acid dyspepsia, through the action of an acid mucus upon an alkaline saliva, swallowed with the food; but this is certainly a rare and minor factor in the production of gas. The regurgitation of carbonic-acid gas from the duodenum may sometimes occur and cause a flatulent distention of the stomach, but this is also a rare phenomenon, and only occurs when the gastric juice is hyper-acid.

Dr. McKenzie, therefore, after discussing all other theories, and dismissing them as incomplete, comes to the conclusion that flatulent dyspepsia is due to a lack of gastric tonicity. In other words, the walls of the stomach, being weak and flabby and lacking in tone, suddenly dilate, and the volume of gas, which was before somewhat compressed, expands and fills out the enlarged viscus. Dr. McKenzie states that the gas does not increase in quantity in the stomach, but only in volume. These two things, quantity and volume, which are identical in the case of solid bodies, are not so with gases. The sudden development of flatulent distention of the stomach, its also rather sudden disappearance, its occurrence in hysterical individuals, the prevalence of flatulent dyspepsia in persons of a weak nervous condition, and the relief obtained by treatment directed to nerve tonicity, are all facts that support Dr. McKenzie's theory. Associated with this gastric atony and, perhaps, dilatation, there is often a slight catarrhal condition of the stomach, which lessens the power of normal gastric digestion, and helps, also, to weaken the walls of the stomach.

The chief thing in attempting to treat flatulent dyspepsia is to use remedies which will increase the nervous vigor, and, hence, according to Dr. McKenzie, tonics, especially nerve tonics, are of the greatest importance. Nux vomica and strychnine are placed at the head of the list. We believe, from statistics collected regarding the frequency of different drugs prescribed in the British Isles, that this drug leads all others, and we have a suspicion that the Englishman has, after all, about as much nervous dyspepsia as the American.

When there is some gastritis associated with this flatulent dyspepsia, and when the tongue is coated, Dr. McKenzie gives a prescription containing bicarbonate of soda, strychnine, spirit of chloroform — which is another inevitable ingredient of British prescriptions — all dissolved in a bitter infusion of calumba or gentian. He gives two ounces of this bitter mixture three times a day, between meals. The English habit of giving large draughts is one which physicians in this country have not adopted, and we doubt if it is necessary.

If there is a good deal of pain in the stomach, as well as flatulence, bismuth is added to the mixture, and a pill containing carbolic acid, valerianate of zinc, and aloine is given. The compound asafœtida pill and the extract of belladonna are sometimes useful.

In enteralgia, when the pain is located lower than the stomach, Indian hemp often answers better than any other remedy, given in doses of one-third of a grain. For the violent spasmodic attacks, which these sufferers often have, associated with distention of the stomach and intestines, a mixture is given composed of equal parts of spirit of cajuput, aromatic spirit of ammonia, and spirit of chloroform; a teaspoonful of this in a wine-glass of water is given every half or quarter of an hour.

Dr. McKenzie does not believe in the use of charcoal in flatulence, nor does he place great stress upon

the value of bismuth. The gist of the paper is, he says, to urge the importance of tonics and antispasmodics, as the rational and effective treatment of flatulence by improving the muscular tone of the stomach.

EXPERT TESTIMONY AS VIEWED IN ILLINOIS.

Illinois is still very far from being completely civilized. Circuit Court Judge Creighton, of Sangamon County, has recently been unburdening his mind on the subject of expert testimony and allied topics, and the burden drops off with a gentle splash that recalls the fall of the buffalo chip, in days when that animal roamed over the judge's prairies. Speaking of experts, he says that "of course the court has no power to compel an expert to make an examination or prepare himself to testify without payment, but he thinks that an expert can be made to testify, provided he is not obliged to make special preparation." From which it seems that the judge thinks the chemist or surgeon or physician can go and testify upon any case, if he chooses, without preparation. The learned judge furthermore says that physicians in Illinois are "favored children of the State." "A department of the State Government," he says, "is maintained very largely for their benefit, and they are so protected by the laws of the State and by public opinion and confidence that in five minutes' time a doctor may earn more than an ordinary laborer could in a day!" If our Illinois *confrères* are really earning $2.00 every five minutes, we trust that the fact will not be made known, for all other regions of the country will immediately lose their medical citizens. The argument that the doctor is so favored by the State that he can earn $2.00 in five minutes is worthy of a giant mind, and deserves to go down in the history of medical jurisprudence emblazoned in letters of gold, or wafted through the empyrean by the swiftest and most characteristic cyclonic whirlwind that the prairies of Illinois can generate. The theory that the State of Illinois has a department of its government—viz., the Health Department—largely for the benefit of the medical profession is also extremely unique and could hardly have come from any mind but one highly trained in Sangamon County. To the common-sense of mankind it has heretofore seemed that the creation of the Health Department was, if anything, prejudicial to the medical profession, since it cuts down mortality and prevents sickness and epidemics, by all of which the medical man is supposed to, and does, gain his livelihood. Medical literature is at least enriched by the marvellous brain of Judge Creighton, which thus, in one single effort, is able to overturn common knowledge and place before the eyes of the astonished world more facts in medical jurisprudence than were ever dreamed of by any philosopher from Descartes to B. O. Flower.

Dr. Lusk's Text-book on Midwifery is to be translated into Arabic for the use of students in the Government Medical School and in the School for Midwives at Cairo.

THE WORLD'S MEDICAL CENTRE.

The history of our schools of learning within the present century shows with what comparative rapidity the centres of great medical activity shift themselves, and it also shows that there is no longer any special great single fountain-head of medical learning, such as used to exist fifty or a hundred years ago. Undoubtedly, in the early half of this century, Paris was conceded to be the great medical centre. The activity and prestige of this school, however, waned very rapidly, and for many years it has possessed few attractions, at least for American students, the foreign student population of Paris being largely Latin and Russian. After Paris, Vienna for a long time was supreme as a medical centre. Of late years this place has to some extent declined in relative popularity. Now, perhaps, medical students find as much at Berlin as at any other single educational centre. We notice recently a claim put forth for Edinburgh as the foremost place for medical undergraduates. Edinburgh, we are told, has more than three thousand medical students, and claims to be as great a place for medical education as it ever was in its palmiest days. Of all the great cities of the world, London alone has failed to make itself felt as an educational centre for medical students. This is due, we presume, to the number of schools and to the absence of a great central educational institution. London is, however, awakening to the fact that it should utilize its vast clinical facilities more efficiently than it has done in the past.

DRUMMING FOR DOCTORS AT HOT SPRINGS.

Probably nothing has placed the Hot Springs of Arkansas and its medical attendants in more thorough disrepute than the practice of drumming up visitors on behalf of the different hotels and doctors. Nothing so absolutely repugnant to the self-respect of all reputable medical men could possibly be undertaken, and we have no doubt that hundreds and even thousands of physicians throughout the country have deliberately warned people against the Hot Springs, on account of their distrust of the physicians who are in attendance there. We are very glad to record the fact, therefore, that some systematic efforts are being made to stop this practice of "doctor-drumming." At a meeting of the Hot Springs Medical Society, held recently, resolutions were passed condemning the practice, and the *Hot Springs Medical Journal* states that "a feeling against this nefarious business is becoming general." The Mayor of the city, even, seems determined to help the good cause. The city council has licensed the business of drumming for hotels and doctors, and it requires now that the drummer shall wear a badge stating his occupation, the object being to put the intended victim on his guard.

We learn that at one time doctor-drumming was stopped through the distribution of circulars on the railroads, warning visitors to look out for the friendly young man who solicited their patronage. This, however, while effective, was found by the city council to be too much against the interests of important persons

in the city, and they stopped the practice. It is hoped that by making the doctor-drummers wear their badge, the business will be lessened if not stopped. A more efficient way, it seems to us, would be to place the ban of absolute disreputability on all physicians who send out drummers.

News of the Week

Award of the Hodgkins Prizes.—The authorities of the Smithsonian Institution have awarded the Hodgkins prizes as follows: First prize of $10,000 to Lord Rayleigh and Professor Ramsey, of London, for their discovery of argon as a constituent element of the atmosphere. Third prize, $1,000, to Henry de Varigny, of Paris, for the best popular essay on the properties of the atmosphere, entitled "L'Air et la Vie." The second prize of $5,000, was not awarded, none of the contestants having fulfilled the conditions. There were 218 papers submitted from all parts of the world, a number of which received honorable mention, coupled in three instances with a silver medal and in six with a bronze medal.

The Cholera is still epidemic in many parts of Russia, although St. Petersburg and the northern cities are officially declared to be free from it. The provinces of Bessarabia, Podolia, Kiev, and Kherson are infected, many towns in Podolia especially suffering severely. In Podolsk recently, the inhabitants took fright as usual at the measures taken to protect them and resisted the erection of temporary hospitals for the accommodation of the sufferers from the disease, and began rioting so fiercely that it was found necessary to call out a body of troops to quell the disturbance.

Yellow Fever is actively helping the insurgent cause in Cuba. A recent despatch states that more than half of the Spanish troops stationed at Vera Cruz have died of the disease, and many new cases are occurring daily. Among the dead was the surgeon of the regiment.

Dr. William A. Betts, of Red Bank, N. J., died on August 4th, aged sixty-one. He was graduated from the College of Physicians and Surgeons of New York in 1861.

A Congregation Struck by Lightning.—During a storm on Sunday last, a Methodist church at Quakertown, N. J., was struck by lightning and over twenty persons in the congregation were injured more or less seriously, and many of them are still suffering from shock. Two among the number are not expected to recover.

The Health of Paris.—Reports were circulated recently on the Continent that a mysterious and fatal epidemic existed in Paris. This the sanitary authorities of the city emphatically deny, affirming that the general health of the city is excellent, that the number of cases of typhoid is smaller than usual, the mortality from diphtheria is almost nil, and that no disease exists in an epidemic form.

Dr. Elias Rodriguez, Professor of Therapeutics and Forensic Medicine in the University of Caracas, Venezuela, died in that city a few weeks ago.

Professor Mikulicz, of Breslau, who was invited to succeed Professor Trendelenburg in the Chair of Surgery, having declined the call, the post has been offered to Dr. Schede, director of the Surgical Side of the Eppendorf General Hospital, Hamburg.

American Editions of Foreign Journals.—The *Annales d'Oculistique* has commenced its fifty-eighth year with an edition in the English language, published in New York under the editorial charge of Dr. George T. Stevens. Commencing with the May number, an American edition of the *British Gynæcological Journal*, the organ of the British Gynæcological Society, was undertaken by Hirschfeld Brothers, of this city.

The Montreal Medical Journal for July comes to us in new and enlarged form and with an increased editorial staff. We congratulate our esteemed contemporary on its improved appearance, which is indicative of a well-deserved success.

The Report of the Pasteur Institute in Paris states that 1,387 patients were treated there during 1894, 7 of whom died. This is 261 less than in 1893. Two hundred and twenty-six of the patients were foreigners, 128 coming from England and only 1 from Russia.

New Orleans is to have a new system of sewerage, which it will take several years to complete and which will cost over $8,000,000.

Vital Statistics of Michigan.—According to the State report for 1893, just issued, there were registered in Michigan during that year 19,197 marriages, 47,722 births, and 21,982 deaths. Of the deaths returned, 2,154 were due to consumption; 1,218 to diphtheria and croup; 689 to typhoid fever; 360 to scarlet fever. There were 644 deaths from cancer, 555 from influenza, and 1,385 from pneumonia.

Cholera in Japan.—In Osaka and Hiogo, Japan, in the week ended July 6th there were 104 new cases of cholera, with 79 deaths.

The American Pharmaceutical Association will hold its annual meeting in Denver during the last week in August. The Brown Palace Hotel will be the headquarters of the Association. It is expected that over one thousand members will be present.

Dr. S. Weir Mitchell received the degree of LL.D. from the University of Edinburgh on August 1st. In the university oration he was described as "the chief ornament to medical science in the New World."

The Report of the New York State Board of Pharmacy for the year ending June 21st shows that 238 certificates were issued during the year, 408 candidates were examined, and 207 were licensed to practise. Ninety-nine candidates were re-examined. There were 33 complaints against alleged violators of the Pharmacy law during the year, and 6 convictions.

A Cholera Antitoxin has been discovered by Dr. Kanson, one of Behring's assistants. It is claimed that experiments upon animals have proved its immunizing and curative properties, but it has not yet been tried in the human subject.

The Italian Congress of Internal Medicine will be held in Rome in October of the present year.

Macao, in China, which escaped the plague last year when it was prevalent in Canton and Hong Kong, has this year been most severely affected. The disease first appeared there in February and has been epidemic ever since. Its neighbors, Canton and Hong Kong, on the other hand, have suffered but little this year.

Dr. Daniel Lewis, of this city, has been appointed President of the State Board of Health.

The Memory of Professor Ludwig Traube has been honored by the placing of his bust in the garden of the Charité Hospital in Berlin. Professor Traube died in 1876.

The Royal College of Surgeons.—Mr. Christopher Heath has been re-elected President of the Royal College of Surgeons, England. Mr. Reginald Harrison and Mr. Pickering Pick have been appointed Vice-Presidents.

The California State Medical Society has reprimanded one of its members for telling a prospective patient that he had succeeded in curing some cases of consumption.

Increase of Lunacy in England.—According to the report of the British Commissioners in Lunacy, recently issued, the total number of lunatics, idiots, and persons of unsound mind was, on January 1, 1895, 94,081, an increase of 2,014 over the number for the previous year. The increase was confined almost wholly to the pauper class, and is due, apparently, to the more general reception in asylums of cases of simple mental decay, resulting from extreme old age.

Laparotomy in a Man Aged Eighty-five.—Drs. J. Greig Smith and C. E. S. Flemming report, in the *British Medical Journal*, the case of a man, eighty-five years of age, suffering from volvulus of the sigmoid flexure. There had been complete obstruction of the bowels for a week, and there was also a small umbilical hernia. Cœliotomy was performed, intestinal drainage instituted and maintained for three days, and the wound then closed. The man made a perfect recovery.

The Charcot Monument Fund now amounts to over 40,000 francs, nearly half of which sum has been contributed by foreigners.

Women at the Door of the Royal College of Surgeons.—At the last meeting of the Council of the Royal College of Surgeons, England, a petition was presented from the London School of Medicine for Women praying that women medical students might be admitted to the examinations for the diplomas of the college. The matter was referred to a committee of the Council for consideration and report. The movement to admit women to the Royal College of Surgeons, and to that of Physicians as well, is strongly supported by influential members of the profession in London, and more or less pressure has been brought to bear upon members of the Council of the College of Surgeons to grant the petition.

A Large Brain.—Dr. G. C. Grant reports in *The Lancet* of July 20th a case of a man, forty-three years of age, who had suffered from epilepsy for seven years and died from congestion of the lungs following a succession of fits. The circumference of the head above the eyebrows was 25½ inches. Clear of all membranes the brain weighed 67 ounces; the convolutions were plump and well formed, and no pathological changes were discoverable except enlargement of both choroid plexuses and a partial ossification of the left one.

Anthrax in New Jersey.—In consequence of a report that anthrax was prevalent in certain parts of New Jersey, a State Milk Inspector was sent to investigate. He states that seventy-two cattle have died in Cumberland County from that disease, and that many others are sick and will probably die. The report has had the effect of preventing the shipping of milk to Philadelphia from the infected locality.

King Christian of Denmark is seriously ill with catarrhal cystitis, and it is feared, by reason of his advanced age, that he cannot recover.

Miss Eleonora Duse, the Italian actress, is reported to be suffering from melancholia, and her condition is such as to cause her friends and admirers much uneasiness.

The Temperance Movement in France.—For some time past French medical writers have been urging the necessity for a resolute stand being made against the ravages of alcoholism. Many of the leading medical journals have inveighed in the strongest language against the heavy mortality from alcohol, compared to which that from cholera is declared to be absolutely benign. In little less than half a century, since 1850, the consumption of alcohol has quadrupled in France, averaging in 1894 four litres per head. Dr. Legrain, Physician to the Insane Asylums in the Department of the Seine, has made an extended study of alcoholic heredity, from which he formulates the following conclusions: 1. Double parental alcoholism creates an irresistible tendency to drinking in the children. 2. Parental absinthism seems to transmit epilepsy directly to the offspring. 3. The parental combination of absinthe drinking and epilepsy is a common cause of epilepsy in the children. Dr. Moreau de Tours says that even children, in certain parts of France, drink large quantities of brandy on holidays. Dr. Roubinovitch, of St. Anne's Asylum, has begun to lecture on drunkenness and alcoholism to teachers and pupils in the schools of his neighborhood, and many other medical men have engaged in the new crusade against intemperance. A French Temperance Society has been recently formed, the members of which do not pledge themselves to teetotalism, but simply to abstinence from spirits and strict moderation in wines, malt liquors, and cider.

The Commission on Leprosy in India has concluded its work. The Commissioners have arrived at the conclusion that the alarm at the spread of leprosy in India is groundless, for they find that the number of cases of the disease has decreased. Many interesting facts and statistics have been brought to light during the holding of the Commission.

An Electrotherapeutic Service, under the direction of Dr. Plicqué, has been established at the Lariboisière Hospital in Paris.

Reviews and Notices.

DEMON POSSESSION. Being an Inductive Study of the Phenomenon of our Times. By REV. JOHN. L. NEVIUS, D.D., (for forty years a missionary to the Chinese). With an introduction by REV. F. F. ELLINWOOD, D.D. With an Index Bibliographical, Biblical, Pathological, and General. Small 8vo, pp. 482. Chicago, New York, and Toronto: Fleming H. Revell Co.

THIS is a curious book, and one written with such sincerity of purpose and painstaking attempt at accuracy that we feel somewhat disarmed in an attempt to criticise it. An author who at this period of our civilization sits down deliberately to establish a thesis that demoniac possession exists, certainly awakens our wonder. The idea that human beings are at times possessed by spirits, evil or good, has certainly never been held by even the average theologian of late years, much less by men who have studied the question medically. The medical view of those cases in which people are supposed to be demoniacally possessed is that they are suffering from epilepsy, hysteria, or insanity. This interpretation is abundantly supported by facts and is sufficient to explain the phenomena; sufficient, at least, for most minds. Dr. Nevius, however, thinks that in certain parts of China demon possession exists, and in proof of this he collects a large number of stories of various people who were, as the people believe, possessed of spirits. The theory of demon possession is ingeniously supported by quotations from the works of medical authors and psychologists and by the teachings of Scripture. There is also appended a chapter upon the facts and literature of the occult. In fact, the book contains a great deal that is curious and interesting to all persons interested in psychology, particularly pathological psychology, and it will have its use even for those who do not and cannot at all believe in the theory that the author tries to maintain.

THE PATHOLOGY OF THE MIND. A Study of its Distempers, Deformities, and Disorders. By HENRY MAUDSLY, M.D. 8vo, pp. 571. London and New York: Macmillan & Co. 1895.

THIS book, according to the author's statement, while retaining the old name is virtually a new work. Much old matter has been left out, fresh matter added, and the work has been quite recast and the text entirely rewritten. While we have no doubt that Dr. Maudsly has done all this, and while we confess freely that the book is a brilliant academic discussion of insanity, we must admit to being personally much disappointed in it. Dr. Maudsly writes from his study for the benefit of literary men and philosophers, and he moves in an atmosphere somewhat superior to that occupied by the every-day alienist. We are sure that a study of such a treatise is useful as an intellectual exercise for those who are preparing to take up the special study of insanity, but for those who are practising this branch of medicine it really has mainly a philosophic and literary value. We would add that we do not think that any man, however experienced or eminent, can write a treatise on insanity in the present day and not give some account of the work and views of others than himself. One would think from Dr. Maudsly's book that there really was no other writer on insanity or practitioner in that branch of medicine. To be sure in his chapter on morbid anatomy, which, by the way, is very inadequate, there is some brief acknowledgment of the work done by Bevan Lewis and Wigglesworth, and we here also find a reference to Meynert and Esquirol, but there is still more about Othello and Desdemona, and the longest quotation of all is from *Les Pensées* of Pascal. Altogether, we must repeat that Dr. Maudsly's book is distinctly disappointing, especially after having read his announcement in the preface. The book, however, perhaps ought not to be judged by ordinary standards. It is really a discussion of the philosophy of the subject, with some finely written clinical pictures, but it is not a practical text-book. Viewing it from this standpoint it deserves great praise for the analytical insight and literary form displayed by the distinguished author.

HYPNOTISM. How it is Done; its Uses and Dangers. By JAMES M. COCKE, M.D. 8vo, pp. 373. Boston: Arena Publishing Company. 1894.

IT is difficult to see, with the excellent works on hypnotism already published by Tuckey, Moll, and Bernheim, the need of another book upon this subject. However, Dr. Cocke asserts that he has had great experience in hypnotizing Americans, and has some special knowledge of hypnotism as it affects his countrymen. We have looked through his book, however, in hopes of discovering some new light upon the subject or some new results from hypnotism as a therapeutic agent, and we find nothing that really satisfies our expectations. The work is a fairly good presentation of the general subject of hypnotism, and the author's views seem to be on the whole not extravagant. His experience in the use of hypnotism with dipsomaniacs is given with some detail, and the fact that the results were so slight gives us a good impression of Dr. Cocke's candor in confessing to the inefficacy of the method in treating this class of cases at least.

THE ELEMENTS OF PATHOLOGICAL HISTOLOGY. By DR. ANTON WEICHSELBAUM. Translated by W. R. DAWSON, M.D. (Dublin.) With eight Plates and a large number of Illustrations in the Text, some of which are colored. Large 8vo, pp. 456. London and New York: Longmans, Green & Co. 1894.

THIS book is a translation by a well-known English pathologist of the work of Professor Weichselbaum. The German author is well known to our readers and his reputation is sufficient to assure us of a sound and useful book. Dr. Dawson has added a few things in his translation, namely, a note on the gum freezing method, and a brief account of Bevan Lewis's method of staining nerve-cells. The general purpose of the author is to provide the beginner in the study of pathological histology with a guide for the work that he is preparing to take up. The various chapters treat, therefore, first, of methods of investigation, which are given in detail and include bacteriological methods. The next part is devoted to general pathological histology and includes various forms of degeneration, progressive tissue changes, inflammation, and infective granulation-tissue tumors. Subsequent chapters include tumors and parasites. The third and last part of the book is devoted to special pathological histology, and this is the part in which the medical practitioner who has already equipped himself for the study of pathology will feel himself most interested. The work is not bulky, it presents the subjects in a thorough manner, and it should form a very useful addition to the physician's library. The typographical work is excellent, though some of the woodcuts have an ancient and familiar air.

THE EXTRA PHARMACOPŒIA. By WILLIAM MARTINDALE, F.C.S., late examiner of the Pharmaceutical Society, and late Teacher of Pharmacy and Demonstrator of Materia Medica at University College. Medical References and a Therapeutic Index of Diseases and Symptoms. By W. WYNN WESTCOTT, M.B. Lond., Coroner for North-East London. Eighth edition. London: H. K. Lewis. 1895.

THE striking feature of this new edition is the incorporation of chapters on antitoxins, serums, lymphs, extracts of animal glands and tissues. Many newer drugs, and especially those of synthetic origin, have received attention, while the preparations recently added to the French Codex and German Pharmacopœia, have been included in the additions. Our previous good opinion of the work remains unchanged, and the druggist as well as the practitioner will find it useful.

DIAGNOSTIK UND THERAPIE DER MAGENKRANKHEITEN, nach dem heutigen Stand der Wissenschaft Bearbeitet. Von DR. I. BOAS, Specialarzt für Magen und Darm Krankheiten in Berlin. II. Theil. Specielle Diagnostik und Therapie der Magenkrankheiten, mit 8 Holzschnitten. Zweite gänzlich umgearbeitete Auflage. Leipzig: Verlag von Georg Thieme. 1895.

THE second edition of this book has been entirely rewritten. It was only a few months after the appearance of the first edition that the author was compelled to enlarge the present one, and owing to the new theories and points of experience gained in the meantime, he has been compelled to change many former chapters. The author starts by dividing Chapter I. into: 1. Gastritis Simplex. 2. Gastritis Infectiosa. 3. Gastritis Phlegmonosa. 4. Gastritis Toxica. A new chapter entitled Gastritis Acida has here been added.

In the chapter on gastric neuroses we find a new clinical picture which the author designates as "Die Schmerzhafte Magenleere," "Painful condition of an empty stomach." We find that he has united the former chapters entitled "Atonie" and "Ectasie," and made one chapter which he calls "Mechanical Insufficiency," in which, however, he still insists that the affections are distinctly different. There are also numerous additions to the pathology and therapeutics of the gastric affections.

While the work as a whole is full of practical points pertaining to the methods, both chemical and clinical, of examining all gastric disorders, still, too much stress cannot be laid on the importance of carefully diagnosticating cancer. And this is really the stronghold of the whole book. Boas's views have been accepted and he is looked upon as an authority in this affection. His papers in *Deutsche med. Wochenschrift*, 1892, No. 17, and in *Münchener med. Wochenschrift*, 1893, No. 43, on the presence of lactic acid as a diagnostic factor in carcinoma are still authoritative the world over. On page 177 of this volume he again reiterates his views, and believes that the presence of lactic acid can be looked upon as a positive proof of the existence of cancer. The aldehyde test of Boas can only be here referred to. At any rate Boas has found that he can frequently diagnose by chemical examination of stomach contents the presence of a cancer long before a tumor can be palpated. We congratulate the author on the successful outcome of the present volume and trust that it will vindicate the claims of a conscientious student and accomplished clinician, and hope the book will be as carefully studied as it really deserves.

Chirurgie de l'Urèthre, de la Vessie, de la Prostate (indications—Manuel Opératoire). Par V. Rochet, Chirurgien de l'Antiquaille, Professeur Agrégé à la Faculté de Lyon. Paris: G. Steinheil. 1895.

The object of this small volume is to point out the indications for operation in genito-urinary diseases, and then to point out the most approved manner of operating.

While not at all intended for the specialist in these diseases, even the skilled surgeon might here and there find something to his advantage.

Illustrations of a schematic order are freely scattered through the text. In one the figures referred to in the description have no corresponding figures on the plate, a fault, which, as the reviewer knows, is often to be laid at the door of the publisher rather than at that of the editor. Just enough regional anatomy is given to refresh the operator's memory and make the steps clear. It is an interesting little work, especially as showing the methods most in vogue in France for bladder, urethral, and prostatic operations.

Diseases of Children and their Homœopathic Treatment. By Robert N. Tooker, M.D. Chicago: Gross & Delbridge. 1895.

The author states that this volume of over eight hundred pages is the outcome of thirty years of practical medical work. It treats of all branches of pediatrics and contains many useful hints.

All modern authors have been consulted and due credit given, so that the book presents a combination of the views of both medical schools and seems to have aimed at giving the best advice, forgetting the homœopathic title of the work.

Laboratory Guide for the Bacteriologist. By Langdon Frothingham, M.D. Philadelphia: W. B. Saunders. 1896.

This neat little book is merely intended as a guide for practical work in the laboratory. It has fulfilled its mission and is full of practical points and directions for rapid diffusion of knowledge otherwise hard to obtain.

La Méthode Brown-Séquard: Traité d'Historique, La Thérapeutique des Tissus, Compendium de Médications. Par le Docteur M. Bra, ouvrage précedé de lettres et préfaces de MM. les Professeurs Constantin Paul, Mendel Ewald, Bruns, Emminghaus, et Byrom Bramwell. Large 8vo, 624 pages. Paris: J. Rothschild. 1895.

Just as we are being told that the method of Brown-Séquard is an entire failure and was but the offspring of a restless senility, we receive a treatise of nearly seven hundred pages devoted to the therapeutics of the tissues. The book, of course, includes much more than the method suggested by the late Dr. Brown-Séquard, for in it we have full directions for the preparation and use of the thyroid gland, the medulla of bones, the pancreatic gland, and the super-renal capsule. The book is preceded by letters from men of eminence, who have continued their commendations of histotherapy mainly to the use of the thyroid gland, or to expressions of general approval of the purpose of the work. The book begins with a history of the method, then a chapter upon the technique of the preparation of organic liquids in general, dosage and methods of use, and we then have separate chapters devoted to the use of the orchitic extract, the ovarian and cerebral extracts, then a long chapter upon the use of the extracts of the heart, pancreas, liver, supra-renal capsule, muscle, kidneys, lungs, spleen, medulla of bones, and of the lymphatic glands. The book is valuable because it classifies and presents a systematic review of all that is known of an important branch of therapeutics, rather than because it shows any remarkable discrimination with regard to the results obtained by the use of this method.

M. Bra says that the book was not originally intended for publication, the substance of it being written for the *Archives*, which the late Dr. Brown-Séquard edited. The death of his distinguished master, however, led M. Bra to think that he could best promote the interests of science and honor the memory of his friend by collecting and placing in book form the observations and experiments which have been made upon the subject of the therapeutics of the tissues.

Traité Clinique et Thérapeutique d'Après l'Enseignement de la Salpêtrière. Par le Docteur Gilles de la Tourette; preface de M. le Professeur J. M. Charcot. Seconde Partie, Hysterie Paroxystique, avec 63 figures dans le texte. 2 vols., 8vo. Paris: E. Plon, Nourrit et Cie. 1895.

This book is a continuation of Dr. Tourette's elaborate work upon hysteria. The first volume was termed interparoxysmal hysteria; the second part is devoted to paroxysmal hysteria. The work begins with a description of hysterical convulsions, and naturally the author follows very closely the description of the different phases of hysteria, as studied and photographed at La Salpêtrière. We find the same old pictures which have served French and other neurologists now for fifteen or twenty years, but which, we must say, do not accurately represent anything that is seen on this side of the Atlantic. The subsequent chapters are devoted to rhythmical chorea, convulsive tic, myoclonus, electric chorea, catalepsy, mania, somnambulism, hypnotism, etc. In the second volume the writer takes up the subject of paralyses and contractures, and then the subject of the visceral manifestations of hysteria. The book, as a whole, is a very complete treatise upon hysteria in all of its aspects. The author announces that it is a treatise on hysteria "according to the teaching at Salpêtrière," and this is to a large extent the case. The book, we believe, would have been a better one if the author had seen hysteria in other countries, and had not written it from so strictly a Salpêtrière and French stand-point, but if the reader bears this provincial characteristic in mind, he will find the book not misleading and, as a rule, most useful to him.

Cystite et Infection Urinaire. Par le Dr. Max Melchior. Chef de Clinique, Ancien Chef de Laboratoire à l'Hôpital Frédéric de Copenhague. Translation from the Danish-French Edition, revised and annotated by Dr. Noël Hallé, Chef de Laboratoire à l'Hôpital Necker. Paris: G. Steinheil. 1895.

This French edition of Dr. Melchior's important work has a preface by Professor F. Guyon, who thinks highly of the work done by the Danish investigator. A historical *résumé* covering the features of the question of urinary infection is followed by a chapter on the technique employed by the author in collecting and analyzing the urine, the steps of which are characterized by the most painstaking asepsis and attention to detail. Chapter III. is devoted to clinical observations and bacteriological investigations. The etiology and pathogeny of cystitis are treated in a most interesting manner. He shows that ammoniacal changes, instead of being the primary and necessary condition for the development of cystitis, are only a contingent phenomenon, often secondary, and due to the action of several varieties of microbes. The therapeutics and prophylaxis of vesical infection, based on clear scientific premises, have an importance which claims attention, and still it is interesting to note how often the conclusions agree with those reached from purely clinical study. The translator has, with the author's sanction, incorporated a number of notes based upon his own laboratory work in the same direction.

Petit Compendium Médical. Quintessence de Pathologie, Thérapeutique, et Médecine Usuelle. Par le Docteur Antonin Bossu, Médecin Honoraire de l'Infirmerie Marie-Thérèse. Third edition, revised and enlarged. Paris: Ancienne Librairie Germer Baillière et Cie. Felix Alcan. 1895.

When we read that this is an enlarged edition we wonder what the earlier ones were, for it is the smallest volume that

one could well think of as a medical work. It does not contain much to interest the American student unless it be used as an aid in acquiring French medical terms. The arrangement is alphabetical, but the word you seek is usually the one which has been left out.

Atlas of the Diseases of the Skin. In a Series of Illustrations from Original Drawings with Descriptive Letterpress. By H. Radcliffe Crocker, M.D., F.R.C.P., Physician, Skin Department, University College Hospital, London; formerly Physician to the East London Hospital for Children; Examiner in Medicine, Apothecaries' Hall, London. Fasciculus IX. Edinburgh and London: Young J. Pentland. New York: Macmillan & Co.

We have already noticed the preceding eight fasciculi of this important work. The ninth begins the second half of the series. The plates comprise lithographs of Hydroa Herpetiforme, Pityriasis Rubra, both of which deserve special mention; Ichthyosis Hystrix and Tylosis, well illustrated in six figures; Psoriasis Punctata, Ichthyosis Congenita, and Lupus Erythematosus. The last-named plate has three figures, showing the affection as it involves the scalp, the face, and the nose. In some instances it is fortunate that the descriptive text contains a history of the case portrayed, since there are occasional departures from the type which would without this not be so clear or instructive. Dermatologists will be much more interested in this production than general practitioners, and indeed few could afford the outlay. There will, as inferred, be sixteen parts at six dollars each. It has the merit of being strictly original, for the most part personal to the author, and the execution has been accomplished with all the modern improvements in the art of plate-making.

The Deformities of the Human Foot. With their Treatment. By W. J. Walsham, M.B., C.M. Aberd., F.R.C.S. Eng., Senior Assistant-Surgeon, Surgeon in Charge of the Orthopedic Department, and Lecturer in Anatomy, St. Bartholomew's Hospital; and William Kent Hughes, M.B. Lond., M.B. Melb., M.R.S.C. Eng., L.R.C.P. Lond.; Orthopedic Surgeon, St. Vincent's Hospital; Assistant-Surgeon, Children's Hospital, Melbourne; Surgical Tutor, Trinity College, Melbourne. New York: William Wood & Co. 1895.

The writers of this work have done a service to their fellows in giving them within the covers of a single volume all that they can possibly need or want to know in respect to deformities of the foot. The only fault is that the writers have perhaps been too thorough in their review of orthopedic practice, and have given the perplexed physician the choice of so many methods and forms of appliances that he is left in almost as much doubt as before. However, the writers always state their preference and practice in the case of the deformity in question, and the reader will not go far astray if he follow them. The work is excellently gotten up, with numerous original and well-executed illustrations of casts and dissections of deformities, and of instruments. The book is one that will serve as a work of reference for the general practitioner as well as a reliable and complete text-book for the orthopedic student and specialist.

A System of Surgery. By American Authors. Edited by Frederic S. Dennis, M.D., Professor of the Principles and Practice of Surgery, Bellevue Hospital Medical College, New York; President of the American Surgical Association, etc., assisted by John S. Billings, M.D., LL.D., D.C.L., Deputy Surgeon-General, U. S. A. Vols. I. and II. Philadelphia: Lea Brothers & Co. 1895.

This system of surgery edited by Professor Dennis is intended to represent American surgery pure and simple, and numbers among its contributors a goodly share of representative men. It is to be completed in four volumes. Although not professedly a pioneer in the matter of strictly American authorship in its own branch it promises to cover the field very effectually and elaborately. The present volumes contain the History and Literature of Surgery, by Dr. Billings; Surgical Pathology, including Inflammation and the Repair of Wounds, by Dr. William T. Councilman; General Bacteriology of Surgical Infections, by Dr. William H. Welch; Symptoms, Diagnosis, and Treatment of Inflammation, Abscess, Ulcer, Gangrene, by Dr. Charles B. Nancrede; Septicæmia, Pyæmia, and Poisoned Wounds, by Dr. W. H. Carmalt; Traumatic Fever, Erysipelas, and Tetanus, by Dr. J. Collins Warren; Rabies and Hydrophobia, by Dr. Herman M. Biggs; Gun-shot Wounds, by Dr. P. S. Conner; Fractures and Dislocations, by Dr. Frederic S. Dennis; Anæsthesia, by Dr. Horatio C. Wood; The Technique of Antiseptic and Aseptic Surgery, by Dr. Arpad G. Gerster; Operative Surgery, by Dr. Stephen Smith; Minor Surgery, by Dr. Henry R. Wharton; Plastic Surgery, by Dr. George R. Fowler; Military Surgery and the Care of the Wounded on the Battle-field, by Dr. William H. Forwood; Diseases of the Bones, by Dr. Nicholas Senn; Orthopædic Surgery, by Dr. Virgil P. Gibney; Aneurism, by Dr. Lewis A. Stimson; Surgery of the Arteries and Veins (exclusive of Aneurism), by Dr. Frederic S. Dennis; Surgery of the Lymphatic System, by Dr. Frederic H. Gerrish; Diseases and Injuries of the Head, by Dr. Roswell Park; Surgery of the Spine, by Dr. W. W. Keen; and Surgery of the Nerves, by Dr. John B. Roberts.

It will be seen that the subjects are reasonably well selected to give variety and interest to the publication, and are unquestionably representative and distributive. Some of the authors have succeeded admirably in their management of subjects, while others have evidently found it impossible to compass many of the important points within the required scope. There is this to be said in qualification, that all the writers are experienced men, and it is fair to assume that the best has been done to fulfil the laudably ambitious endeavors of the talented editor. The article by Dr. Billings is a masterpiece of thoroughness, but is much too long for a work of this size. The articles on surgical pathology, bacteriology, septicæmia, and traumatic fever are models of their kind and amply fulfil the expectations of their readers. The same may be said of those on antiseptic and operative surgery, and on fractures and dislocations. The indexes are by no means as complete as they ought to be in a work of this kind. The work is profusely illustrated, is fairly printed, but very slovenly bound.

Abstract of Sanitary Reports. Vol. IX. Washington, D. C. 1895.

Volume IX. of this interesting and instructive series is of unusually large size, and contains much valuable material for the student of public health. The supervising surgeon-general of the Marine Hospital is to be congratulated on the success of his endeavors to so admirably systematize the work of his bureau.

The History of Prostitution, its Extent, Causes, and Effects Throughout the World. By William W. Sanger, M.D., late Resident Physician Blackwell's Island, N. Y., etc. 8vo, pp. 709. New York: American Medical Press.

This work, first published over thirty years ago, again makes its appearance with additions and comments from the well-known syphilographers, Drs. R. W. Taylor, Prince A. Morrow, and F. R. Sturgis. The elaborate study of the subject by the original author gave it long since a leading position as a thoroughly scientific contribution to a much tabooed topic. The chaste and discretionary methods of presentation prove how much science can make pure everything it touches. As the title indicates, the work treats of prostitution from the earliest times to the present in every country. To the student of sociology the data are of more than ordinary interest, as proving how even general and varied effects depend upon common and well-recognized causes. The question of control of prostitution by legal enactments is very fully discussed, and all its different aspects are quite impartially considered, not only in reference to its bearing on social questions, but what is equally important, to the possibility of control of sexual disease...

Treatment of Fractures by Massage and Mobilization (Movement). By Dr. Just Lucas-Championnière, Surgeon to Hospital Beaujou, Member of Academy of Medicine, President of the Surgical Society of Paris. Paris: Rueff & Co. 1895.

This work is a distinct innovation regarding the generally accepted treatment of fractures by rest and immobility. The author believes that massage in given quantity and quality should be the essential feature in the treatment of all cases of fracture, and more particularly in those involving the joints. His arguments in favor of his method are ingenious, and in some respects are quite plausible, especially such as refer to the maintenance of stimulated circulation as an important element of repair. His remarks on the necessity of maintaining mobility in joint fractures commend themselves to the good judgment of surgeons, and altogether the work is a very suggestive one, and from such a

stand-point is well worthy of perusal. The very novelty of the ideas advanced will doubtless attract much attention to this work. As might be expected the author does not favor splints save in exceptional instances, but prefers well-adjusted bandages, after massage has, according to him, done its perfect work.

THE FILTRATION OF PUBLIC WATER-SUPPLIES. By ALLEN HAZEN, late Chemist in Charge of the Lawrence Experiment Station of the Massachusetts State Board of Health. 8vo, pp. 197. New York: John Wiley & Sons. 1895.

THE author has presented a very thorough work on the subject in question, dealing with all the different varieties of filtration, and offers some very conclusive arguments in favor of its adoption in all the usual methods of water-supply. The work also contains a very instructive appendix giving the German official regulation in regard to filtration.

TRANSACTIONS OF THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. Vol. VII. 8vo, pp. 336. Published by the Association. 1895.

THIS volume contains a very good variety of practical subjects bearing upon surgical and gynecological matters and will take a worthy place with its predecessors.

VITAL STATISTICS OF BOSTON AND PHILADELPHIA FOR SIX YEARS ENDING MAY 31. 1890. By JOHN S. BILLINGS, M.D., Deputy Surgeon-General United States Army, Expert Special Agent. 4to, pp. 266. Washington, D. C., Government Printing Office. 1895.

THIS is a very elaborate and instructive report of the vital statistics of the cities named, and contains their divisions in sanitary districts, indicating the prevalent diseases of the same as shown by maps in different colors. Compiled as they are from the health-board reports they are as reliable as they can be made, and present statistical information which is of the greatest value to the statistician and hygienist.

BURIED ALIVE. An Examination into the Occult Causes of Apparent Death, Trance, and Catalepsy. By FRANZ HARTMANN, M.D. 1895.

THIS work treats in a very serious mood the possibility of being buried alive, relates some probable instances of such a calamity, and insists upon the value of putrefaction as a test of actual death.

Clinical Department.

A CASE OF PRIMARY POST-PARTUM HEMORRHAGE — PUERPERAL SEPTICÆMIA AND DEATH.

By W. D. HUMPHREY, A.M., M.D.,

VIRGINIA, ILL.

IN the April number of the *American Journal of Obstetrics* a case of "Secondary Post-partum Hemorrhage—Septicæmia and Death," was reported by Dr. E. L. Tompkins, of Washington, D.C. I desire to report a case of "Primary Post-partum Hemorrhage—Puerperal Septicæmia and Death." In the former case the hemorrhage was due to disturbance of the nervous system, mental grief. In the latter, the hemorrhage is of an entirely different origin.

I was summoned by a messenger on Sunday morning, February 17th, to the residence of Mrs. C. F. C——, who resided three miles in the country. I arrived about seven thirty, and found her engaged in the second stage of labor, with the third child. I barely had time to get my coat off and thoroughly disinfect my hands when the labor was abruptly terminated. I handed the child to the attendant, and was preparing to extract the placenta, when I felt another head presenting. In a few minutes the second child was born, and in a short time the large placentæ were expelled, but the uterus failed to retract. In less time than it takes to tell it, a violent hemorrhage occurred. The flood-gates seemed to have been thrown wide open, for the blood gushed out in a perfect torrent. An immense amount of blood was lost. It soaked through two or three thicknesses of an old quilt, a mattress, and formed a large pool on the floor. The patient was rendered pulseless and collapse seemed imminent. I had the head lowered, placed hot irons to the extremities, administered ergot by the mouth, and injected hypodermatically whiskey and digitalis. I introduced one hand into the vagina, and with the other grasped the uterus through the abdominal wall. Under the above methods the uterus soon contracted and hemorrhage was under control. Whiskey in a little hot water was given occasionally. The pulse soon began to improve in force, and by noon the patient had rallied from her perilous condition. I saw the case in the afternoon about four o'clock. She was able to talk and laugh some. Pulse still improving. Temperature, normal. I ordered a saline laxative to be given in the morning, which moved the bowels freely. I called again on Monday morning and found her feeling quite well. Temperature, normal. Uterus, well contracted. She complained of nothing, except occasionally of after-pains. After giving the necessary instructions I left, expecting that all would be well; but such was not the case. She was taken with a chill on Monday night about nine o'clock. I was not sent for until Tuesday morning. The temperature then was 104° F.; respiration, 40; pulse, 120. She complained of intense pain over uterus. There was some slight tenderness, but the abdomen was not tympanitic. The skin was hot and dry; the tongue was dry and covered with thick brown coat, and the thirst was intense. The lochial discharge was scanty and quite offensive. I remained all day Wednesday. The temperature was 105° F.; pulse, 140; respiration, 40. The intense thirst continued. The face was pinched and bore an anxious expression, and was occasionally bathed in profuse perspiration. It now began to assume a livid hue. Great irritability of the stomach began and continued with unabated frequency. She vomited a large quantity of black, grumous matter, which proved to be disintegrated blood, indicating an extensive capillary hemorrhage from the walls of the stomach. She continued to grow worse, and died comatose at nine o'clock Wednesday, about seventy-two hours after the confinement.

It is hardly necessary to go into details in regard to the treatment of the case. Strict antisepsis was carried out. Treatment was local and constitutional. A three per cent. solution of carbolic acid and creolin was employed for irrigating. Alcohol and quinine were administered internally, and they, together with cold sponging, proved most useful in reduction of temperature. By cold sponging the temperature was reduced from 105° to 102° F., but it returned again to the old mark in two hours.

The important point to call attention to is the cause of hemorrhage. While inertia of the uterus is probably the most frequent cause, there are others of equal importance. Inertia is most often manifested after a rapid or an exceedingly long labor; or it may be due to great distention of the uterus, as in twins, polyhydramnois, etc. Although due to the above factors, it is frequently associated with certain pathological conditions. In this case I do not think that the inertia was due entirely to the rapid labor and extreme distention of the uterus, but to a deranged condition of the blood. The primary cause was, no doubt, of constitutional origin; and if the full history of the case could have been elicited the exact condition might have been known, but it was probably splenic anæmia or some allied condition. The puerperal septicæmia which followed had no connection whatever with the hemorrhage. They are separate and distinct conditions, and the former was not a sequence of the latter. I am unable to account for the origin of the septicæmia which destroyed this woman's life. I know that this awful disease, this terror of the puerperium, is due to the

introduction of septic bacteria into the genital tract. Puerperal septicæmia is heterogenetic and contagious. The doctrine of autogenesis has been exploded. The poison must come from without, and in this case either the attendants or physician were to blame. I am able to exonerate myself, from the fact that I was not attending on any contagious disease at the time, and had employed antiseptic precautions. The husband of the patient, being exceedingly penurious, refused to employ a nurse until it was too late. She was, therefore, attended by persons who had no experience whatever in the management of such cases, and did not receive the proper care and attention which she ought to have had.

DOUBLE OVARIOTOMY IN A WOMAN SEVENTY-ONE YEARS OF AGE—RECOVERY.

By F. F. LAWRENCE, M.D.,

COLUMBUS, O.

The following case presents some features not frequently encountered by the abdominal surgeon, viz., the extreme age of the patient, the size of the tumor, the fusion of the cystic and solid growths, each having separate pedicles, the cyst from left, and solid from right side; and, finally, the complete recovery of the patient.

Mrs. B——, aged seventy-one, first noticed a tumor two and a half years ago. The growth was very rapid. In April, 1894, she was tapped and thirty-eight pounds of fluid removed. The sac refilled rapidly, and was again tapped in November, when fifty-eight pounds were removed. The tumor rapidly refilled, and in January, 1895, she was again tapped, but owing to the occurrence of shock only thirty-four pounds of fluid were withdrawn. After the second and third tappings there was some peritonitis. After the third tapping a large solid mass was discovered in right side.

The operation was performed on February 16th. There were extensive adhesions to the parietes, intestine, omentum, diaphragm, and bladder. While I was breaking loose the broad band of adhesion to the diaphragm respiration stopped. Aside from this, the operation was without incident. On turning out the tumor it was discovered to have two distinct pedicles. That from the left side being long and broad, and in it the left Fallopian tube could be noted. That from the right side to the solid portion of the tumor was broad and short, and contained the right Fallopian tube. Both pedicles were tied off; the numerous adhesions were tied and the wound closed, a drainage-tube being inserted in the lower angle. The patient was put to bed forty-three minutes after the beginning of the administration of chloroform. Shock was quite severe. The drainage-tube was removed at 3 A.M. on February 17th. The progress from that on was uneventful. The patient sat up in bed on the fourteenth day, and in the chair on the sixteenth day.

The weight of the tumor was eighty-four pounds. The cyst is a simple multilocular one. The solid portion is not simply adherent to the cyst, but there is absolute fusion.

Another feature of the case worthy of note is, that in 1887 the woman had right hemiplegia, which did not entirely disappear for two years. Up to the present date, March 8th, there has been absolutely no indication of any trouble of any kind. The highest pulse has been 88, and the highest temperature 99.2° F. So that I presume it is fair to call it a complete surgical recovery. To-day the patient is sitting up and feeling "better than for years."

103 North Fourth Street.

P.S.—After the patient was convalescent—in fact, after she had been sitting up for ten days or more—she had an apoplectic seizure, resulting in complete right hemiplegia, involving even the muscles of deglutition to such a degree that it was necessary to feed her per rectum for five days. She died thirty-two days after operation, and yet from a cause in no way connected with the operation, as she had been the victim of right hemiplegia (in a less degree) seven and nine years ago; *i.e.*, this was the third attack.

VAGINAL HYSTERECTOMY FOR CARCINOMA OF THE NECK OF UTERUS.

By A. ERNEST McMAHON, M.D.,

MARSHALL, TEX.

About five weeks since I was called upon to operate upon a patient of Drs. Blalock, of Woodlawn, Tex., and Baldwin, of Ferns, Tex., for carcinoma of the neck of the uterus. Hemorrhages had been very severe, but as yet no fixation had taken place, so I decided to perform vaginal hysterectomy. The patient was a white woman, very anæmic, and forty-three years of age.

After preparing patient and anæsthetizing her, Dr. Baldwin administering the chloroform, I proceeded to operate, and removed the uterus by the method described by Dr. Garceau, in the *American Journal of Obstetrics*, March, 1895.

The patient has made a complete and uninterrupted recovery—at no time did the temperature go above 99° F., and she is now enjoying good health and walking about.

The operation of vaginal hysterectomy I consider a good one whenever it can be carried out, and all that is necessary is a thorough knowledge of the anatomy of the parts and a careful operator.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Tuesday Evening, May 21, 1895.

Louis Faugéres Bishop, M.D., Chairman, pro tem.

Further Report of Achylia Gastrica.—Dr. Max Einhorn read the paper (see p. 5). In discussing the subject Dr. Fenton B. Turck said that the paper was a most excellent one, and he had no criticism to offer upon it, yet he wished to say that he saw no reason for the name achylia gastrica. That which was called achylia was a symptom and must be due to some pathological cause, and he thought the name was hardly justifiable as being applied to a symptom. The glandular elements of the stomach seemed to suspend their functions for a time, but the motor elements remained active. The same nerves controlled both these functions, and paralysis would cause the paralysis of both, but as the motor function was not affected it could not be considered a paralysis with atrophy of the glands. Dr. Stewart, of Philadelphia, had found cases in which there was a return of glandular activity after suspension for a period of nine years, so it seemed possible that in some cases there might be partial atrophy of the glandular elements. This partial atrophy might be due to anæmia, or to a lack of nutrition, for the glands must receive a proper amount of blood, and if this, for any reason, was insufficient, the secretions would be suspended, but would appear with the return of the proper blood-supply. This was illustrated in shock, where there was an arrest and then a return of the blood-supply. He had known of cases in which the glandular secretions had been restored by the use of hot water and massage, and one case in which, after an absence for three years, hydrochloric

acid was obtained by irritation of the mucous membrane for fifteen minutes with the gyrometer.

The cases which the writer had mentioned in his paper were especially interesting as showing that the mucous membrane was not necessarily affected. An analogy of this condition was found in a number of organs of the body, as in the kidney where there was a suspension of function without atrophy of the glandular structure. He had obtained from the stomach in which glandular activity had ceased shreds of mucous membrane, and found on examination that the glands were not atrophied.

Dr. Louis F. Bishop thought the author of the paper deserved much credit for the work which he had done upon the subject. It took a great deal of time and care in carrying out the investigations. The work of applying the different tests, and the extreme care that was necessary to avoid error, made the task very arduous.

In closing the discussion Dr. Einhorn said he thought he was justified in giving the name achylia, as it was possible for patients to get along very well without the gastric juice if the intestines had adapted themselves to that condition. Moreover, he did not see any reason for not giving the name when the whole line of treatment depended upon this condition found in the stomach. In some cases there was atrophy of the glands and in some not, and if, after a time, there was a return of gastric juice, it must be concluded that there was some other reason for the previous condition than the atrophy of the glands.

The Flechsig Method in the Treatment of Insane Epileptics.—Dr. L. Pierce Clark read the paper on the above subject. He said that the treatment and the etiology were so closely related that he would have to mention them together. It was his opinion that trauma, as an etiological factor, had been over-estimated, for friends of the unfortunate patient would easily remember some fall or slight injury that had been received at sometime, and thus would the conclusion be reached that trauma was the cause. Heredity was undoubtedly the most important factor in the etiology of epilepsy, and he believed that it was the cause in more than fifty per cent. of the cases. There was no doubt that in many families it was Nature's law of the survival of the fittest, for these persons were not fit to propagate the species, and so Nature placed her seal upon one as a criminal, another as a consumptive, etc., but as the physician could not judge, he had to do the best he could to relieve the condition as it was found.

It could be reasonably hoped that the researches that were being made as to changes in the nervous system and the degeneration of the nerve-cells would throw more light upon this subject of epilepsy. There were patients who contracted epilepsy, though living under good conditions and at that age when least expected, *i.e.*, fifty to sixty years, and others seemed to get well of themselves.

The bromide treatment had held its sway, and, though good, yet in most cases, and especially in cases of epileptic insanity, it only held back the attacks for a time, and finally there was a breaking over. It was seldom given, therefore, with the idea of effecting a cure, but by helping to restrain the fits it made matters easier for the keepers.

In order to give the Flechsig method of treating epilepsy a trial, the writer had used it on ten patients in the Connecticut Insane Asylum. The first patient had a history of hereditary epilepsy, and fifteen years ago had begun to have epileptic fits, and at present has about the intelligence of an eight-year-old child. The bromide treatment had restrained the attacks for awhile, but they had broken over the restraint. She was put on the opium-bromide treatment, and though the attacks were less frequent for a time, they returned, but she was more easily managed.

In the second patient the attacks were rendered less frequent, but the stupor was increased and the dementia hastened. The third patient gave the peculiar history of contracting acute Bright's disease during the opium treatment. It was generally agreed that the bromides act upon the epithelium of the kidney, and it was probable that in this case the opium had just begun to have an effect, and the bromide caused the albumin. The opium affected the fourth patient very badly and the gastric disturbances were severe.

The fifth case was a woman, forty-seven years of age, with a history of hereditary epilepsy. She had the first fit on her twelfth birthday and since then at various times. The bromide treatment affected her badly at all times and the opium had no influence for good. The treatment increased her stupor. The sixth case received no benefit from the opium treatment. When the seventh case was put upon it the patient said he felt better, but the number of fits was increased. He improved on the bromide treatment, but was the only one that did. The eighth case was very much reduced in strength by the bromide necessary to have an effect, and opium rapidly increased the dementia. The ninth patient enjoyed the drowsiness produced by the opium, which increased the stupor and dementia. The tenth patient suffered from aura rising from the epigastrium to the third rib, and an accumulation of saliva, so that when speaking it sounded like a blubbering through water. This case was somewhat uncommon in the fact that the expulsion of saliva often took the place of the fit. The patient improved for a time under the Flechsig treatment, but within seven months the power of control had ceased.

It seemed proper to conclude, therefore, that there was no fixed law by which we could prescribe, and we were forced to the conclusion that the Flechsig treatment was little better than the bromide treatment.

Though epilepsy was a mental degeneration, the body was generally healthy. Muscular exertion had a tendency to sustain the bodily health. The question was important whether the restraining of cell explosion gradually diminished the tendency to explode, or whether it was but a damming back for a time, to be followed with a severer outbreak with its consequent effects. It seemed proper to conclude, at least, that the use of the opium treatment was of little value.

In discussing the preceding paper, Dr. Frederick Peterson stated that he had tried the Flechsig method of treating epilepsy with opium and bromides in a large number of cases since the publication of the new treatment by its author. In cases which resisted ordinary methods, in the obstinate chronic cases with frequent attacks where nothing seemed to avail, it often produced very beneficial results. It is a means which should only be resorted to, he believed, in this particular class of epileptics. Certain cases which he had observed had presented some of the mental symptoms characteristic to the disease, and in these the opium-bromide treatment had on several occasions proved surprisingly useful. In some private patients he had employed codeine in the place of opium with success. He had less fear of inducing the opium habit when codeine was used, though with due caution opium could be given without any particular danger.

Dr. Joseph Collins said he thought trauma was a very important factor in the etiology of epilepsy, and cited a case of a boy that had been treated for hysteria, but an operation demonstrated Jacksonian epilepsy from trauma. He thought the plan of treatment of the patients referred to in the paper was not carried out as Flechsig's method required, for the opium treatment had not been continued long enough, and the amount of bromide following was not enough. It was his opinion that in opium the practitioner would find a drug that would be of great benefit in the treatment of epilepsy. In cases of long standing, where the bromides would not have an influence, the desired effect

could be produced by the use of opium. He remembered a patient who was brought to the clinic last fall by a policeman, and whose mother said that he was generally out of his right mind for two or three days, and then would get better for a few days. He was put on the opium treatment, and was now able to earn his living, was much improved mentally, and had had only three or four attacks.

As to the statement that the effect of the opium would be lost in eight or twelve months, he would like to ask what would be the objection to repeating the treatment. Had anyone seen the opium habit formed by it, or the health injured? He thought not. As there was a close relation between the epileptic fits, the dementia, and the cell degeneration, he did not think it was fair to take those who were so near dementia to test the effectiveness of the treatment. If it was expected to control the cells, it was important that the cells be not so degenerated that they could not be affected. Flechsig had kept his patients under observation for five years, they had observed theirs for one year, and he did not think we ought to accept as conclusive the author's cases which had been observed for only two months. He thought the Flechsig method was an important measure in the treatment of epilepsy.

Dr. T. H. Manley said he thought trauma in producing epilepsy was of minor importance. He had treated cases by trephining and had seen others do the same, and had never seen one in which perfect recovery took place.

In closing the discussion Dr. Clark said Dr. Collins had had a more favorable lot of patients to treat than his own. The reason why he did not continue the opium treatment longer was that he had to stop it or lose his patients' lives. He thought that dementia was much more rapid in those cases of hereditary epilepsy.

At the close of the meeting Dr. Fenton B. Turck, of Chicago, presented several instruments which could be used in the diagnosis and treatment of gastric disturbances. The gyrometer was valuable in determining the size of the stomach, the resistance of its walls, in washing it out, and for stimulating its walls by a kind of massage. He also presented and described an instrument for the introduction of oil of cloves and cinnamon into the stomach in the form of spray, so there would be no irritation of the mucous membrane, yet the walls of the stomach would be thoroughly disinfected. This instrument was made with double tubes so that air which might be pumped into the stomach during the treatment could escape and nausea be thus obviated.

The next instrument presented was for determining the muscular power of the stomach, and consisted of a dilatable rubber bag that communicated with an apparatus which recorded the slightest variation in pressure. When the rubber bag had been introduced into the stomach it was inflated and the power of the muscular contraction of the stomach was recorded. It was hoped that by extended investigation there could be determined a gastric unit which would be valuable in diagnosing atonic conditions of the stomach. He also presented an instrument for diagnosis of stricture or obstruction of the œsophagus. With this the examiner could judge as to the consistency of the obstruction or the extent of stricture by the resistance communicated to the hand. It was also easy to tell when the bulb of the instrument had passed into the stomach.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, April 25, 1895.

Henry C. Coe, M.D., Chairman.

Fatal Case of Umbilical Hemorrhage in a Newly Born Child.—Dr. Charles E. Nammack reported the case. (See p. 191.)

Uterus Containing Fully Developed Fœtus Removed Post Mortem.—Dr. S. Marx presented a uterus, with a fully developed fœtus and membranes, removed post mortem from the body of a woman who had died during labor from some obscure pulmonary trouble.

Dr. Garrigues remarked that such specimens were rare, and this one had been very nicely preserved.

United Twins.—Dr. Teinberg presented photographs of female twins united at the coccyx by a band two and a half inches long, and five inches in circumference. They were born on April 15th, and were reported in the daily papers as another instance of Siamese twins. The labor had been very puzzling, and the union of the twins was not recognized until the birth of the second one. They weighed about nine pounds, and were doing well. They were joined from the top of the sacrum to the tip of the coccyx, and the two coccyxes were undoubtedly amalgamated. There was only one anus, but the rectum was believed to bifurcate above. The external genitals were placed farther back than normal. All organs were believed to be separate, excepting the common anus. There was a normal placenta of one childbirth. The common cord bifurcated about an inch from the placenta, one branch going to each child. The question of separating the twins would come up later. The speaker was disposed to think it could be done successfully by a plastic operation.

Multiple Fibroids of the Uterus Removed by Abdominal Section.—Dr. Paul F. Mundé presented a uterus containing multiple fibroids which he had removed about six weeks ago by abdominal section from a single woman, thirty-two years of age. As he had stated on former occasions, he was not disposed to remove the uterus for fibroids unless the symptoms gave plain indication, and in the present instance two years had passed between the time when he had first seen the patient and the operation. He had left a little of the cervix in order not to destroy the vaginal roof.

Fibroid Removed Through Vagina.—Dr. Mundé also presented a fibroid tumor of the cervix uteri, in a virgin of forty-one years, removed with some difficulty through the narrow vagina after cutting into the capsule of the tumor, inserting forceps, and spreading the blades in order to obtain a firmer hold. The perineum and vagina were torn. The rents were sewed up and the patient made a good recovery. The tumor weighed two pounds. In a former similar case the tumor had weighed three pounds. Dr. Mundé said he had several times been called upon to remove fibroids which had become vaginal in elderly virgins, oftener than in women who had borne children.

Dr. H. L. Collver was reminded of a case which he had seen in Connecticut, one of fibroid tumor of the uterus filling the vagina, which had been mistaken by the local physician for inversion of the uterus. The woman has borne many children. The perineum was torn to the third degree; the tumor filled the pelvis so completely that he found extraction impossible until he had made a V-shaped incision, cutting out the larger central portion.

Twin Pregnancy with Blighted Fœtus, Illustrated with a Case.—Dr. Grace Peckham-Murray read the paper. (See p. 711, vol. 47.)

The Chairman, Dr. Coe, said that a few months ago he had shown a second fœtus, acephalic, poorly developed, which lived but a few hours. He supposed it would be classed under the head of blighted fœtus, blighted from overgrowth of the other fœtus, which was fully developed.

Triplet Pregnancy with Blighted Fœtus.—Dr. E. A. Tucker showed photographs of a case at the Sloane Maternity, triplets, two of which were born alive, the third mummified and flattened. The author of the paper had mentioned the fact that in many cases it was difficult to determine the cause of death, but in this instance it could be shown that the fœtus had caused its own death by twisting the cord and shutting off the circulation. There had been plenty of room for its devel-

opment, as there was hydramnios. The two living babes were small, but had plenty of vitality. There were three distinct placentæ and sacs. The third had undergone so-called fatty degeneration, which he believed had followed, not preceded, the death of the child. All three children were females. The mother was thirty years old. It was her fourth pregnancy.

Cæsarean Section Versus Symphyseotomy, with Report of Cases.—Dr. Edward P. Davis, of Philadelphia, read a paper on this subject. The case of symphyseotomy was in a slightly built negress, who had registered before her confinement at the hospital dispensary, but who was not taken to the hospital until a number of hours after the commencement of labor and efforts had been made to engage the head by posture and by forceps. The external pelvic measurements were: Anterior superior spines, 22 ctm.; iliac crests, 23.5 ctm.; trochanters, 27.5 ctm.; external conjugate, 19 ctm. The patient was a primipara, aged twenty-seven. Finally her husband consented to her being taken to the hospital in a carriage, where symphyseotomy was performed. On opening the symphysis the pubic bones separated an inch and a half and the child's head immediately descended to the pelvic floor. Extraction was made with Simpson's forceps; the child was asphyxiated, but was resuscitated. The cranial diameters were large: Biparietal, 11; bitemporal, 9; occipito-mental, 14 ctm. The uterus was packed with iodoform gauze, the symphyseotomy wound was also tamponed with iodoform gauze and closed, except that the last suture was left untied. The vaginal wall had sustained injury by the head. A band of adhesive plaster was drawn around the trochanters. For eighteen hours the patient passed no urine and the nurse made unsuccessful attempts to introduce the catheter, after which catheterization was performed successfully by a medical assistant, and the following night the patient urinated spontaneously. She died on the third day following delivery. The child survived. It was thought infection had taken place through the vaginal injury, which was due to the unusual breadth of the child's head, 11 ctm., instead of 9 ctm., which was the ordinary breadth, and also to the inelasticity of the vagina and vulva. Then, too, the patient's powers of resistance to germ infection had been diminished. The case showed that the obstetrician, before choosing symphyseotomy, should study carefully the elasticity of the vagina and vulva as well as the pelvic and cranial dimensions.

The case of Cæsarean section was also in a negress, aged eighteen; strong family history of tuberculosis; poorly developed; height, four feet, eight inches; illegitimate pregnancy. Pelvic measurements: Iliac spines, 23 ctm.; iliac crests, 24 ctm.; external conjugate, 17 ctm.; true conjugate, 7.75 ctm. Right and left diagonal unequal. After careful pelvic measurement and attempt to determine the size of the child's head, it was decided best to induce labor, as the pregnancy was near full term. After the patient had been in labor twenty-seven hours, following the introduction of a bougie, Dr. Hirst agreed with Dr. Davis that it was best to perform Cæsarean section and make it impossible for the patient to become pregnant again. Consequently the abdomen was opened, the child extracted from the uterus, and the uterus removed. The patient made a good recovery, and was now nursing her own child and also helping to nurse another. The child's head measured: Biparietal diameter, 8.4 ctm.; occipito-frontal, 11.25 ctm. The child's weight was four pounds and fifteen ounces. It was evident from the measurements that the method of delivery was based on relative indications. The indication for cœliotomy in his judgment rested not merely upon the small size of the mother's pelvis, but also upon her illy developed birth canal and her failure to make the child engage by spontaneous effort. Had the Saenger operation been done, leaving the uterus, the patient would have been exposed again to illegitimate pregnancy. Only a year and a half ago a woman had been submitted to the Saenger operation in Philadelphia, and was now suffering the disappointment of a second pregnancy.

Regarding the permanent results of symphyseotomy, Dr. Davis had delivered two other women by this method, in neither of whom could any abnormality now be discovered in the pelvis.

In conclusion, Dr. Davis said his experience in five symphyseotomies had led him to believe that the operation was a child-saving one, as in these cases the children had been saved where otherwise no alternative remained but craniotomy or delivery through the abdomen. One of the cases was taken from a tenement-house while the patient was suffering from pneumonia, and she survived the operation two days. The cases reported this evening led him to believe that symphyseotomy was most successful in women not weakened by prolonged labor, in whom there was slight contraction of the pelvis, no great disproportion between the pelvis and head, and in women in whom the vagina and vulva were well developed and distensible. The Saenger operation was indicated where there was marked disproportion between the head and pelvis, as shown by failure of the head to engage, where the vagina was poorly developed, and in married women who were willing to run the risk of a future pregnancy. Where, as in his case, the patient had a poor constitution and was liable again to pregnancy, he would advise cœliotomy followed by hysterectomy.

The Chairman, Dr. Coe, mentioned as among the chief points for discussion in connection with Dr. Davis's paper, 1, an elective operation depended not so much upon the mere presence of pelvic deformity as upon disproportion between the head and pelvis; 2, supra-vaginal hysterectomy as oposed to the Saenger operation; 3, the ultimate results of symphyseotomy, which he was sorry to say had not been so good in this city as in some others; 4, that symphyseotomy ought to be an elective operation, and was most apt to be successful where there was not too great disproportion between the head and soft parts.

Five Cases of Symphyseotomy.—Dr. J. Clifton Edgar thought the discussion was a little premature in its bearing upon the relative value of symphyseotomy and cœliotomy. He believed that about seventy-four cases of symphyseotomy had been reported in this country, with a maternal mortality of twelve or fourteen per cent. The mortality from the Saenger operation was known to range anywhere from one per cent. up to forty. Undoubtedly if cases of late operation were ruled out the mortality from symphyseotomy could be reduced almost to nothing, as it had been done in the Saenger operation. Some time ago, Dr. Reynolds, of Boston, had gone over the statistics of the world with regard to the Saenger operation, and had collected thirty-nine cases in which the operation was done within twenty-four hours after the onset of labor, no previous attempts at delivery, no complications except bony obstruction, and all these patients had recovered. The operations were done by thirty different operators. Under the same circumstances equally good results should follow symphyseotomy.

Symphyseotomy was not in any sense a simple operation. In the majority of cases, too, it was attended with subsequent complications, but of these we had heard little from Europe, although, no doubt, they occurred there as elsewhere. It had been claimed that there would not be danger of injury to the vagina and bladder unless the pubic separation were extended to four inches. But it had been shown in Italy that the vagina began to be stretched at 7 ctm., and there was dangerous stretching at 10 ctm.

In reviewing his five cases, Dr. Edgar said that in none did the pubic separation approach four inches; in one there was marked hemorrhage from the vessels of the clitoris; in one there was vaginal laceration and

the woman still had a sinus, although she was in good condition. The permanent results were good, for in two of his patients, observed a year or two after the operation, no evidence existed of injury to the pelvis. It had been shown in Italy that the periosteum on the front of the pubic bone would stand stretching 7 or 8 ctm., and if this were not cut through with the knife solid union would take place more quickly. Necrosis of the bone did not mean that the woman was doomed to be a cripple, for in one of his cases suppuration and necrosis took place, and although the convalescence was protracted over five months, yet the woman was now able to do laborious work.

Dr. Edgar had found attempts to estimate the size of the child's head by pushing it down into the mother's pelvis rather unsatisfactory. Faraheuf had invented a kind of forceps for measuring the child's head.

All of Dr. Edgar's cases of symphyseotomy had been in tenements. In one the conjugate before symphyseotomy measured 3.25 inches; in the next labor the woman was delivered by version.

Dr. W. T. Lusk could report two cases of symphyseotomy. The first patient had been submitted to various efforts at delivery before admittance to the hospital and was in a dying condition. Symphyseotomy was done to save the child. The mother died after seventeen hours, and the child also died after eleven hours, having had its jaw broken before he saw the patient.

Dr. Lusk had had a second case quite recently, in a patient aged nineteen, in the Infant Asylum. The estimated antero-posterior diameter was 3 or 3.25 inches, the transverse very narrow. The woman had been in labor nineteen hours, the cervix was pretty well dilated, the head was still above the brim. The conditions for operation at the hospital were not very good. During the operation he remembered many times a statement of Pinard, that no man should undertake symphyseotomy without having a chain-saw at hand, and he regretted that he had none in this instance, since for a part of the distance the symphysis presented bony union, and it took him thirty minutes to effect division when under ordinary circumstances it should have required not more than three minutes. The rest of the operation was simple, and was performed after the manner which he had lately seen practised by Pinard in Paris. Performed in this way, very little blood, not more than twenty drops, need be lost. In his case the pubic bones were not separated more than 6 ctm., by measure with the instrument used in Paris. The child was extracted with forceps, without any injury to the soft parts. An attempt was made to sew up the fibrous tissue in order to hold the symphysis together, as suggested by Faraheuf. The patient died seven days after the operation, with all the symptoms of septic peritonitis. The autopsy showed that the symphysis was zigzag, partly bony, and that a saw would have quickly divided it. The sutures had not held and there was considerable separation. The uterus, tubes, and ovaries were healthy. There was peritonitis, and the intestines were glued together. Dr. Lusk said he would not think of undertaking symphyseotomy in a tenement or under conditions which did not offer the best opportunities for antisepsis. The trouble in this case had arisen from the fact that separation of the pubes had stripped off the periosteum to quite a distance, the tissue had necrosed and led to infection.

Dr. Lusk was not sure but what under similar circumstances he would on another occasion choose Cæsarean section. On going over the statistics of symphyseotomy he had found that the great successes had been confined to comparatively few men, who had operated under favorable conditions.

Symphyseotomy Has a Limited Field.—Dr. Charles Jewett thought symphyseotomy would hold a prominent place in obstetrical surgery, but the fact became very obvious as experience increased that its field was a narrow one. In equally competent hands Cæsarean section and symphyseotomy had given about the same success. Symphyseotomy labored under two marked disadvantages. In the first place, its use was determined by little more than half an inch variation in the diameter of the pelvis. If a mistake were made in its indication it might be fatal to the child and prove dangerous to the mother, whereas if one chose Cæsarean section the chances for both mother and child would be good. The other disadvantage under which symphyseotomy labored was the great difficulty in the after-care, whereas in Cæsarean section this was very simple. If sepsis already existed, especially in the uterus, symphyseotomy was preferable to simple Cæsarean section, but the latter operation followed by removal of the uterus gave the mother as good a chance as symphyseotomy.

Named for the Wrong Men.—Dr. H. J. Garrigues said he had had an equal experience with Cæsarean section and with symphyseotomy, having done both operations twice. One of the patients submitted to Cæsarean section died, all the others lived. The first case of Cæsarean section was of some historical interest, since it was the first one performed according to the so-called Saenger method after Leopold's two cases, while Saenger himself was eighth in the list of operators by this method. The only original idea of Saenger connected with Cæsarean section was to cut out a piece of the muscular tissue of the womb and then fold in the peritoneum, a thing which was speedily given up. In this country, too, we heard of the Trendelenburg position, while in Germany they did not so name it, for the position had been used by Badenhauer in 1881, and probably earlier by Billroth. Trendelenburg had only popularized it.

Where symphyseotomy was applicable, Dr. Garrigues decidedly preferred it to Cæsarean section. It was safer. He had operated once in a dirty house, but he would never do it again if it were possible to convey the patient to a hospital. He might say that in his second case the pubic separation by actual measurement was five inches, yet no damage was done. This great amount of separation had taken place while the patient was under the care of assistants who knew little about symphyseotomy. He was resuscitating the asphyxiated child in an adjoining room. As to statistics in Germany, they performed Cæsarean section if the case were known to be aseptic; otherwise they took their chances with symphyseotomy, which, of course, made a worse showing for the latter.

Two Cases of Symphyseotomy.—Dr. Edward A. Ayres had had two cases of symphyseotomy which he had not yet reported, one last autumn, the other on Monday preceding the meeting. The conjugate in the first case measured $3\frac{1}{2}$ inches. The child died before it could be extracted, hence craniotomy was performed. The pubic bones separated three-fourths of an inch. The mother made a perfect recovery. In the last case the conjugate measured $3\frac{1}{2}$ inches, the separation was a little over two inches, the child weighed nearly ten pounds, but its heart had ceased to beat before it was brought into the world. The mother was fleshy, and much difficulty was experienced in bringing the pubic bones together again. She was now doing well. Dr. Ayers spoke very highly of the bed used in the Polyclinic Hospital in these cases. A wire mattress bed, a wooden frame on top with canvas stretched across it, a hole in the canvas at the buttock, rope and pulley to lift the wooden frame. One strong argument in favor of Cæsarean section was the much smaller fœtal mortality. He did not think the fœtal death-rate following symphyseotomy would be greatly reduced below twenty-six per cent. Regarding the method of extracting the child, Dr. Ayers said that internal version had never been a favorite procedure with him, and in symphyseotomy it would increase the fœtal death-rate.

Dr. G. W. Jarman remarked that these women did

not always fall into the hands of men of much operative experience, nor were hospitals always accessible, and he would ask Dr. Davis which, in his opinion, was the safer procedure for men of limited experience, Cæsarean section or symphyseotomy.

Six Cases of Symphyseotomy.—Dr. Coe thought stress should be laid on the point made by Dr. Ayers, namely, that symphyseotomy was intended as a life-saving operation for the child, and when it failed in this it failed of its purpose, for a dead child could be extracted through a pelvis of such dimensions by craniotomy. They had had six cases of symphyseotomy at the Maternity Hospital within a comparatively short period of time. One of the children died. In this case the cervix was well dilated. The child was not large. Dr. Coe had expected an easy delivery after symphyseotomy, and was surprised at the difficulty of getting the head through. Version had been performed. There was no doubt but what the mother could have been saved as well by Cæsarean section as by symphyseotomy, and the child would not have died. In cases of elective Cæsarean section the child had been extracted with ease, and the mother had made a smooth recovery. Against symphyseotomy was the difficulty of determining the size of the child's head. He had had one case of at least half an inch separation of the pubes six months after symphyseotomy, and the patient walked with a waddling motion. There were probably other similar cases which had not been reported. Such a result in some families would prove a very serious affair.

Dr. Davis closed the discussion. Replying to Dr. Jarman's question, he thought that under the circumstances named the general practitioner, with the assistance of a single cool-headed medical neighbor, could do Cæsarean section more safely to mother and child than symphyseotomy.

Stated Meeting, May 23, 1895.

Henry C. Coe, M.D., Chairman.

Cephalopagus.—Dr. Charles E. Nammack presented a double fœtal monstrosity, the principal and the parasite being joined at the head. Abortion had taken place about the fifth month. The specimens had been preserved for some months before he saw them, so that they were useless for studying the blood-supply.

Conservative Vaginal Gynecology.—Dr. H. N. Vineberg presented specimens from two cases. The first patient had suffered from backache, migraine, profuse menstruation. He found retroversion of the uterus in third degree, with marked prolapsus of both tubes and ovaries, but he was unable to make out distinct disease until he had made an incision in front of the vagina. The left tube was thickened, the left ovary contained some small cysts, which he punctured and returned the organs to the abdominal cavity. The right ovary contained a cyst as large as an almond, which he incised, whipped over the defect with running catgut, returned the organ, and fixed the uterus to the anterior abdominal wall. The girl had been well since, and expressed herself as feeling like a different person. To his mind the uterus was now in ideal anteversion.

In the second case the patient had suffered from a good many symptoms relating to retroversion which he had corrected in a similar manner, leaving the organ in good anteversion. There was still some pain from a thickened tube.

Ectopic Pregnancy.—The Chairman, Dr. Coe, presented a specimen of tubal pregnancy, and stated that the case impressed the danger of delay. The patient gave a history of having skipped one period and thought she was pregnant. The night before, when her period was due, she had very severe abdominal pain. On examination, some hours later, Dr. Coe found a small uterus, but an enlarged left tube. That was all, and there were no subjective symptoms at this time, the pulse and temperature being normal. He made the diagnosis of possible ectopic pregnancy, and requested to be notified at once in case symptoms arose. Symptoms did arise that night, but they failed to notify him until the next afternoon, when she was practically moribund. He gave an absolutely bad prognosis, but operated, found the abdomen full of blood, and death occurred soon afterward. He believed that if he had insisted on operating when he first saw the patient her life would have been saved.

Dr. Nammack thought the cause of delay was the teaching of the books that the hemorrhage might take place into the broad ligament, instead of into the free cavity, and become shut off and cause no further trouble.

Cœliotomy for Fibroids.—Dr. Francis Foerster presented large fibroids from three cases, removed with the uterus through the abdomen. The first tumor and uterus weighed fifteen pounds. This case was complicated by pregnancy at the seventh month. The woman had been almost exhausted by hemorrhages. Scarcely any blood was lost during the operation. She recovered. The second specimen was a large myomatous tumor of the uterus, pus tubes, and an ovarian cyst the size of a child's head. The patient had suffered since the birth of her child eighteen years before. She was extremely anæmic and shock was profound. She died on the third day.

The tumor and uterus in the third case weighed twenty pounds. This patient had also suffered greatly in general health from hemorrhage, etc., was jaundiced, the heart beat 120 to 140. Little blood was lost, but as a precaution he injected three hundred grammes of salt solution. She was doing well since the operation two days ago.

The Chairman thought it was remarkable that Dr. Foerster's patient with large fibroid had not died of shock. The success of the operation was probably due in no small degree to beginning with stimulants in advance of it, instead of waiting, as many operators did, until shock had set in.

Pregnancy and Labor Complicated by Cardiac Disease.—Dr. Julius Rosenberg read a paper on this subject, giving the histories of two cases seen by himself, and reviewing some of the meagre literature on the subject. He thought it probable that the reason why the subject had received so little attention was the fact that mild cases of cardiac disease complicating pregnancy were probably overlooked, while the severe ones ended fatally and therefore remained hidden. His first case was in a German woman, aged thirty-two, in labor with her first child. The pains had continued about fifty hours when he was called. The os was fully dilated, but the pains were feeble, and no progress was being made. There was a distinct systolic murmur at the apex. Forceps were applied and a living child was extracted. The patient was doing well until she suddenly became cyanotic, pulse rapid and irregular, and in spite of every means to restore her she died within three hours.

The second patient consulted him when she was six months pregnant. She had had chorea during childhood which had left her with a damaged heart. She had atonic dyspepsia, eructation of gas, presystolic murmur, displacement of the heart to the left, œdema, bronchitis. He had often thought of emptying the uterus, but concluded that the best chance was given by letting pregnancy go to term. Evidences of venous obstruction increased, fluid was present in the pleural cavities, there was cyanosis. Labor came on somewhat prematurely. The patient's condition becoming alarming, he used forceps in order to terminate labor. A living boy was extracted. The uterus contracted and the placenta was expelled within twenty minutes. The heart continued to act poorly for a time, but later improved somewhat. Four hours after labor she was

seized with a convulsion. The heart failed and she died.

Experience had shown that, excluding milder cases of cardiac trouble complicating pregnancy, a large percentage of the cases proved fatal. The immense risk which women with cardiac disease ran in becoming pregnant made it imperative that marriage be forbidden. If one's advice were not followed, every means should be taken to put the patient in good general condition. The question whether delivery should be hastened was a grave one. Unfortunately the hope had proven delusive of saving the patient by inducing labor when the cardiac symptoms were marked.

In order to allow the heart to accommodate itself to the arterial changes after labor, delivery of the placenta should not be hastened. During the lying-in period the heart required constant watching. Simple diet and proper stimulation formed the basis of treatment.

Dr. Coe called attention to the fact that the period of greatest danger to these patients was for a short period after labor. He said Dr. Grandin could relate a case bearing on that point.

Dr. Egbert H. Grandin thought the author's experience was unique in that he had seen two cases of bad cardiac diseases complicating pregnancy within a short period of time, but it was not unique in the result. Few of us saw enough cases of this kind to dogmatize as to management. The woman with cardiac disease might go through her first pregnancy, possibly her second, without special difficulty, simply because the cardiac lesion was compensated by hypertrophy. It was when this compensation ceased and dilatation began that danger arose.

As to marriage, if the heart lesion were not of aggravated type he would not forbid it, for the reason that the large majority of women with minor cardiac lesions did marry, bore children, and suffered no ill consequence. If the heart disease were of an aggravated type, marriage should be forbidden. As to treatment, he would advise emptying the uterus just as soon as there was cardiac dyspnœa, particularly if there were albumin in the urine. When one decided to empty the uterus, the sooner it was done the better. In spite of the fact that chloroform was regarded as dangerous in cardiac disease, he would prefer to administer this anæsthetic during induction of labor.

Dr. Simon Baruch related a case, seen with Dr. Dana twelve years ago, that of a primipara with cardiac insufficiency, in whom the pains were ineffectual. While they were debating what to do, the nurse came out of the lying-in chamber and said the patient had suddenly expired. He then made up his mind that if he should ever see a pregnant woman with advanced mitral disease, he would at once empty the uterus.

Dr. Simon Marx had seen about six cases of cardiac disease complicating pregnancy, in two of which his experience was rather sad, although the ultimate result had been favorable. He believed the large majority of pregnant women with cardiac disease got along without trouble, but where dilatation took place the danger was great. He was a great believer in nitro-glycerine, for it was both a cardiac stimulant and vaso-motor dilator, and did not irritate the kidneys like strophanthus and digitalis. One of his patients, a young woman, in good circumstances, had passed through her labor well, then went into collapse from heart failure. He resorted to heroic treatment, injecting one twenty-fifth of a grain of nitro-glycerine every hour for ten hours, and also a high rectal enema of a quart of salt solution every hour for ten hours. Not until then did she begin to recover. He attributed the collapse in this case partly to ergot. This drug was faulty in these cases, inasmuch as it acted as a vaso-motor constrictor, not as a dilator.

Dr. Mary Putnam-Jacobi queried whether cardiac thrombosis was not the cause of death after labor in these cases, for the conditions were favorable for this accident.

Dr. Anna M. Galbraith related a case of marked cardiac insufficiency in which the woman passed through labor successfully, bearing a living child.

Dr. R. A. Murray said the only cases in which he had found trouble were those of mitral disease with systemic symptoms before pregnancy occurred. Pregnancy usually rendered these cases worse, both during the early and the later months. Œdema of the feet and lungs and cardiac dyspnœa were danger signals. He had seldom seen these symptoms without a fatal issue before or after confinement. There was, however, even a more dangerous form of heart disease, viz., fatty degeneration without valvular lesion. He had seen one such case, in a very large woman, who had coma and vomiting before labor. The child was delivered, she improved somewhat, but died without the nurse being aware of it. In the case of a young woman he advised against marriage on account of a fatty heart, but the advice was not followed. Dr. Lusk saw her during pregnancy, and his assistant induced labor at the fourth month, but she died. Labor should be induced early.

Dr. Rosenberg did not know why labor should be induced when the symptoms of cardiac disease were slight. When they were serious, the prognosis was bad under any circumstances.

A Contribution to the Nature, Cause, and Treatment of Suspended Animation in the New-born.—Dr. J. D. Bissell read this paper. The first case of suspended animation in which he had tried prolonged suspension occurred in a child to which he was hastily summoned at the New York Asylum for Lying-in Women, September, 1893. He arrived almost immediately, but found the child to all appearances dead. Having had some experience with suspension in chloroform asphyxia, and observing that a spark of life remained, he had the child suspended by the feet. Breathing and heart action were soon partly restored, but stopped at intervals, and it was fully twenty minutes before a voluntary movement was observed of the head or arms. The child was then placed in the horizonal position, but as it grew weaker, a pillow was arranged and its head was allowed to hang down. It was six hours before complete recovery took place. At the end of two weeks it left the hospital healthy. The cause of the trouble was unknown.

Not long afterward he had opportunity to try this method in suspended animation in the new-born. The fœtal heart action had been strong, but before the end of labor there was marked loss of blood, the heart action became weak or ceased. Extraction was hastily performed. The child was pale, there was general complete muscular relaxation, no apparent heart or respiratory action. The inverted position had to be persisted in in this case for two hours. At first very weak gasps set in; after the first hour they became a little deeper, and finally regular. The child was feeble, but showed excellent health by the twenty-first day.

The third case was also one of suspended animation in the new-born, the first gasp occurring three minutes after delivery, being followed immediately by flow of mucus from the mouth. The next fifteen minutes there were five or six short breaths. At the end of an hour and twenty minutes after suspension was begun the lungs and heart were found acting normally. The peculiar feature of this case was the succession of rapid breathing for fifteen or twenty minutes, and intervals of two or three minutes without breathing.

Dr. Bissell had attended four other cases in which there was suspended animation of the new-born, and resuscitated them in a similar manner. As soon as delivery was completed the child was held up by the feet, mucus was cleared from the mouth or throat by a cotton swab, the child was wrapped in a warm blanket, the cord was severed if there was no pulse; the child

was taken near a stove and the inverted position was maintained until resuscitation had taken place. Of other methods the best were those of Schultze and Dew. He thought there was some danger in the manipulations of Schultze's method, and as to inflation of the lung, death was apt to result from too much force, besides air was likely to be driven into the stomach as well as into the lungs. Other methods were mentioned.

Suspended animation in the new-born might be due to impairment of the umbilical circulation from pressure upon the cord, entanglement of the cord upon itself or around the child, to loss of blood, or to shock following injuries. It might be of apoplectic, cyanotic, or anæmic form. In either case the circulation demanded primary consideration, and it was through improvement of this that we must look for awakened activity of the nerves covering respiration. Life could be sustained several minutes after birth without respiration through the lungs, provided the heart action were kept up. The latter might be too feeble to be recognized, constituting suspended animation, not actual death, in which case the heart would be enabled to work with greatest advantage by placing the child in the inverted position. Each inspiration increased the amount of oxygen in the system until the function of respiration was fully established. The suspended position also favored expulsion of mucus. The method could be used in combination with others, but Dr. Bissell had practised it alone in order to give it a fair test.

The paper was discussed by Drs. Dew, P. A. Harris, R. A. Murray, Rosenberg, Jarman, Amende, and the discussion was closed by Dr. Bissell.

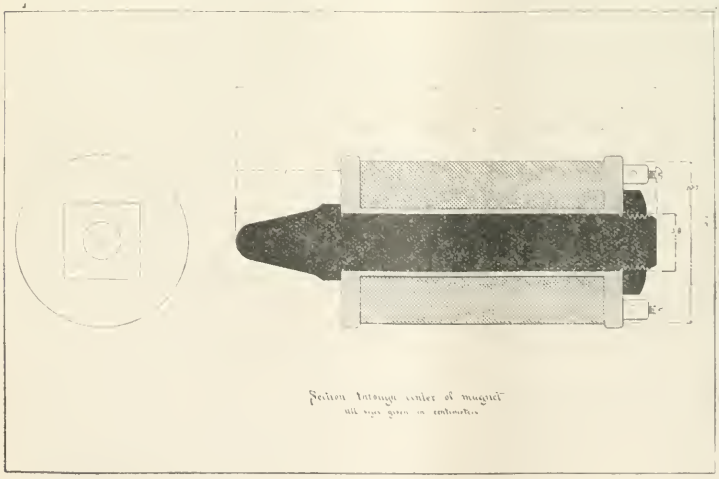
New Instruments.

THE ELECTRO-MAGNET FOR THE REMOVAL OF FOREIGN BODIES FROM THE EYE.

By H. G. SHERMAN, M.D.,

CLEVELAND, O.

No persons who present themselves to the oculist cause greater anxiety than those giving a history of an impaction of a foreign body in the tissues, or a penetration and a lodgement of the same within the chambers of the eye. It nearly always happens that the point of entrance and lodgement of a foreign body is difficult to make out, owing to hemorrhage or swelling. Should a foreign body be lodged in the tissues of the eye or its chambers, it is of the gravest concern, for we know with almost absolute certainty that sooner or later an irido-clycitis or irido-choroiditis will supervene with probable loss of the eye in case the foreign body cannot be safely extracted. We know also of the almost certain involvement of the integrity of vision of the other eye sympathetically in case of violent inflammatory reactions occurring in the injured eye. Therefore, any means which will aid in the certain diagnosis of the presence of a foreign body within the eye and assist in its removal will be heralded with satisfaction. The great majority of these cases lead one to look for iron or steel, and while various magnets have been employed with varying success for the removal of these bodies through open wounds, I am not aware that an electro-magnet has been devised capable, when properly energized, of detecting with absolute certainty very small particles of iron or steel which may be imbedded deeply within the eye and the presence of which cannot be made out by any clinical evidence. The writer has enjoyed great satisfaction in the use of an electro-magnet made for him by Mr. Adams, of the General Electric Company, Cleveland, O. The magnet is made of soft Norway iron, of the single-bar type, of a size and shape as indicated by the photo-engraving. It was energized by the current from the electric (incandescent) light wires in my office. About twelve ampères and an electro-motive force of one hundred and twelve volts, developing a resistance force of about one hundred and twenty-five pounds to the square inch, was found sufficient to draw small particles of iron and steel from masses of various organic substances employed for experimental purposes, the details of which I need not enter into. The following cases will better illustrate the value of this magnet:



Section through center of magnet
all sizes given in centimeters

Case I.—Miss Katie W—— was referred to me by Dr. Sabin, of Warren, O., June 22, 1894. The history of the case gave evidence that six weeks previous to the consultation, while employed by the N. Y. P. & O. Electric Light Co., she was struck in the eye by a foreign body, supposed to be a filament of bamboo which she was grinding at the time of the accident. Dr. Sabin, whom she consulted, observed a slight cut in the conjunctiva about one line from the corner and the superior margin of the lower inner quadrant of the eyeball. At that time the doctor did not suspect the presence of a foreign body in the eye, the vision being normal, although the girl complained of constant pain and a great abhorrence to light, with excessive lachrymation. At the time of consultation with Dr. Sabin I found those same symptoms obtaining; in addition a marked circumcorneal, deep-seated injection existed, acute sensitiveness over region of original injury, determined by probe and pressure. The ophthalmoscope revealed hyperæmic conditions of the optic disk; vision was found to be normal. An incision was made through the conjuctiva at point of injury and cicatrix found in sclera. I did not deem it advisable to make an exploratory incision in the scleratory tissues without more positive evidence of the presence of a foreign

body. I therefore advised that atropia be employed to keep the eye at rest, and that the eye be properly protected from the light; also that the girl be kept under strict observation and await developments. During the next five months I saw the girl several times, but gained no additional knowledge in regard to the causation of the pain, etc., which had been more or less constant since the time of injury. Various analgesics were employed without avail. In November I learned that the girl's eye might have been injured by a small particle of steel, as a nick was discovered in the knife of the machine at which she was working at the time of injury. Acting on this information I had the magnet constructed. On November 25th the girl's eye was brought near the magnet energized as above described. When within twelve inches of the magnet she complained of a sharp cutting pain in the eye. The magnet had determined with absolute certainty the presence of iron or steel within this girl's eye. November 30th Dr. Sabin was sent for, and we prepared to make an incision through the tunic of the eye and remove the foreign body. The patient refused to allow the operation to be made; no argument would avail, and, recognizing the possibilities in the case, I refused to assume further responsibility. In order, however, to convince Dr. Sabin of the presence of a foreign body within the eye I determined to again apply the magnet. Twelve ampères at an electro-motive force of one hundred and twelve volts was employed, and the eye placed in direct contact with the magnet cone, with the unexpected result of withdrawing through the tissues (sclera and conjunctiva) of a piece of steel wire 2 mm. in length and $\frac{7}{10}$ mm. in diameter, two lines inferior to the point of entrance. Considerable hemorrhage followed the exit of the foreign body. Shortly afterward the patient returned to Warren with vision unimpaired, with no untoward symptoms whatsoever, and is now employed at her old work.

Case II.—April 4, 1895, Joe D——, boiler-maker, presented himself at my office with the statement that a piece of steel struck him in the eye. The chambers of the eye were filled with blood, preventing an ophthalmoscopic examination. A wound in the sclera was found, the magnet brought into action, and a piece of steel 9 mm. in length and 3 mm. in diameter was removed through the wound aperture. I was obliged to remove the eye on account of the violent inflammatory reaction which came on a few days later, and found on examination that the foreign body had lodged in the tunic of the eye at the fundus near the optic disk.

Case III.—The latter part of April Dr. Perkins came into my office with Robert D——, in whose cheek a piece of steel had imbedded itself deeply three weeks previous. The magnet immediately detected the point of location; an incision through the integument was made and the steel instantly clicked against the magnet.

Case IV.—May 2d, John B—— was brought to my office with a bit of iron impacted in the iris of the right eye, having penetrated the cornea. A corneo-scleral section was made and the iron withdrawn by the magnet, carrying with it a segment of iris which was excised.

Many cases of iron chips implanted on the cornea have been removed by placing the eye in direct contact with the magnet cone. Sufficient has been noted, I trust, to determine the value of this form of a magnet as a sure means of diagnosis where the presence of iron or steel is suspected.

Hiccough in the new-born is a symptom of hereditary syphilis. The effects of specific treatment on the hiccough are marked.—Carini.

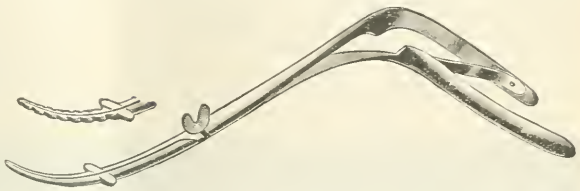
AN IMPROVED UTERINE DILATOR.

By J. W. LONG, M.D.,

Richmond, Va.

In 1890 I published an account of a uterine dilator, which instrument possessed several points of advantage over any dilator then on the market. Recently I have improved this dilator in a number of particulars, and feel sure that a trial will prove it to be a superior instrument.

It is made in two sizes. The smaller one has smooth small blades, so that it is readily introduced into even a "pin-hole os." The ordinary dilator is too blunt for such cases and cannot be introduced without first enlarging the external os with a sound or "boring" into it with the point of a scissors. The blades "feather" just enough to keep them from slipping out, while the shoulder gauges the depth of introduction. The joint is fastened by a thumb-screw, which is easily removed; this is only necessary when the instrument is to be cleaned. The female blade should be made a little stouter just opposite the thumb-screw than is shown in the cut. The handles are curved downward and backward, throwing them and the hand holding them entirely out of the way of inspection and manipulation while the dilator is *in situ*. A spring between the handles keeps the blades closed.



The large-sized dilator has corrugated blades, and the handles may be fitted with a thumb-screw, but it is questionable whether or not a thumb-screw is desirable.

This instrument is manufactured by Messrs. Bartlett, Garvens & Co.

THE HORIZONTAL POSITION FOR APPLYING PLASTER CAST.

By T. W. SLOAN, M.D.,

Seattle, Wash.

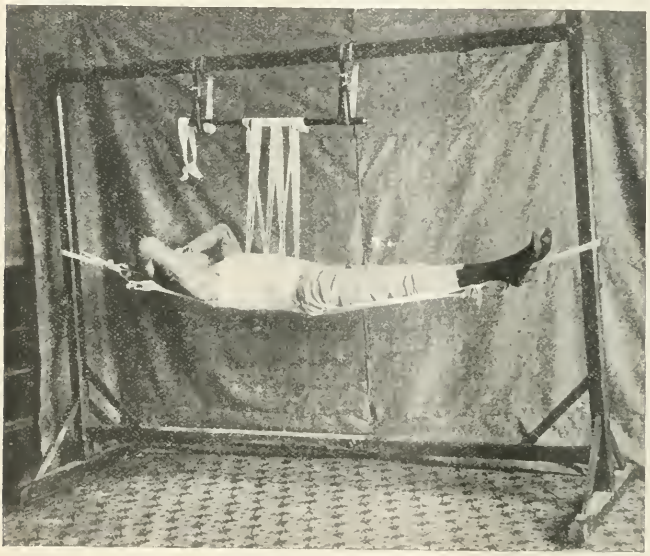
This apparatus is one by the use of which we are enabled to properly apply a plaster jacket for supporting the spinal column in any case requiring artificial support. Never was there a saying more pregnant with truth than that necessity is the mother of invention. It was on account of the difficulties in the way of applying a cast in the upright position, and the unsatisfactory results often following its application in that way, that led me to devise a method which is more simple, more efficient, and at the same time one which gives the patient the greatest degree of comfort possible while the jacket is being applied.

This apparatus consists of a frame eight feet long and six feet high. A hammock made of canton flannel, double thickness, from nine to fifteen inches wide according to the size of the patient, and a few inches longer than the patient to be treated, is stretched between the two upright pieces. To the top rail of the frame is suspended a pole by two straps with buckles, so that the pole can be raised or lowered at will by the operator. This completes the description of the apparatus.

The patient should be divested of all clothing covering the trunk save a closely fitting knit shirt, and if we are dealing with Potts' disease a pad of absorbent cotton should be placed on either side of the processes of

the diseased vertebra and held in position by one turn of a bandage around the body, after which the patient is placed upon the hammock. With emaciated patients I prefer enveloping the body in a layer of absorbent cotton, which is easiest accomplished by laying strips across the hammock before placing the patient upon it. The end of a roller bandage is now attached to the suspended bar, and about three turns of the bandage are taken around the body and up over the bar, leaving an interspace between each turn of the bandage. The turns of the suspension bandage should be drawn sufficiently tight to cause the hammock to fit the concavity of the back, and after securing the bandage to the bar, they can be further adjusted, if necessary, by raising or lowering the bar.

After first applying a dry roller bandage, the plaster bandages are applied and should be carried from the trochanters to the axillary spaces. The number of plaster bandages necessary is from four to ten five-yard ones, according to age of patient, the latter number being sufficient for an adult. It is also necessary to



This patient, being carefully measured before and after, showed an increase of one inch in height, no extension being made.

place a pad of folded towels or like material over the stomach and one over the chest, under the shirt, so that they can be easily removed after the cast becomes set, thus allowing the patient plenty of breathing-room and room for digestive purposes.

When the cast has been applied, the patient is left undisturbed a sufficient length of time for it to harden, which should be not less than two hours in any event. After it has become sufficiently firm the patient is placed upon the feet, and the two ends of the hammock, with the suspension strips, are cut off even with the cast. It will sometimes be found necessary to trim off the edge of the cast under the armpits to let the shoulders down to their natural position, and also to trim out in front of each groin sufficiently to allow the thighs to be flexed at right angles with the trunk.

Since I first called the attention of the profession to this method of applying a plaster jacket by an article published in the MEDICAL RECORD, March 10, 1894, and by sending out some photographs later on of my improved apparatus to some of the leading surgeons of the country, I have received a number of letters and have been very much gratified on account of the interest manifested. Some suggestions have been offered as to improvements that I might make, only one of which I will mention, and that is of adding traction for the purpose of making extension upon the spinal column, while the jacket is being applied. This suggestion, coming from so eminent a source as Dr. Lewis A. Sayre, should not pass unheeded, for he says: "If you will now add to it traction by the head and feet, to overcome the reflex muscular rigidity while you are applying the plaster, you will make the thing perfect." Now, I take the position, and my experience in the use of this apparatus confirms me in the opinion, that muscular rigidity is overcome by this position alone, and that strong extension is never required after we have secured muscular relaxation by a comfortable reclining posture. The steady, firm pressure exercised upon the muscles of the back while the patient is being suspended in my hammock apparatus will control muscular spasm with no less certainty than a well-applied bandage controls muscular spasm in a leg or an arm. In the treatment of Potts' disease I have found that no extension whatever is required, except where there is lateral displacement, in which case gentle traction made upon one foot, while the shoulders are being supported, will be sufficient to bring the vertebral column into line. To extend the spine forcibly while we have at the same time secured muscular relaxation is not only unnecessary, but it is certainly not entirely devoid of danger. I have carefully measured the height of each patient upon whom I have applied the plaster jacket, no extension being made at the time, and have found an increase in height, after application of the cast, of not less than three-fourths of an inch, showing conclusively that in this position we have muscular relaxation, which is the one condition absolutely necessary for securing extension of the spine.

Permit me here to quote the opinion of a man to whom we are all indebted, perhaps more than to any other man living, for the wonderful advancements during recent years in the surgery of the abdominal cavity — I refer to Dr. Nicholas Senn. He says: "I thank you for the photograph, and congratulate you on your exceedingly simple and efficient method of extension." That expresses, in one short sentence, just what it is, for it is an extension apparatus exceedingly simple and exceedingly efficient. To my mind this method is in every way superior to the time-honored one of suspension in the upright position, and I can think of no condition calling for the use of the Sayre apparatus which is not fully met by it.

1. The patient experiences no pain in consequence of the operation.

2. In this position we secure muscular relaxation, without which we cannot hope to achieve the best results.

3. This position is most desirable for securing perfect adaptation of the cast to the patient's body.

4. Time is not limited as in the upright position, and we are not compelled to rush through with an operation the result of which depends upon the amount of care we exercise.

5. In this position we secure the nearest approach to absolute quiet, with regard to muscular movements, both voluntary and involuntary, including respiratory movements.

6. Fatal syncope can never occur in this position in consequence of the operation, as has sometimes happened with feeble patients while being suspended in the upright position.

7. After the cast has been completed the patient can be left quiet and comfortable in position a sufficient length of time for it to harden—a thing not possible in the upright position.

A NEW MYRINGOTOME.

By CORNELIUS WILLIAMS, M.D.,

ST. PAUL, MINN.

THE best instrument for myringotomy I believe to be a small curved knife, which Mr. Meyrowitz, of New York, has made for me and which is sufficiently described by the illustration. The knife is a slight modification of a capsulotome which I have used for several years. The advantage of the curved blade over the straight in capsulotomy, after extraction of cataract, is that it cuts more readily, and in the sweep of the knife it makes a longer hole in the membrane. Another advantage is that it will cut old capsules which are only pushed along and torn from their ciliary attachments by the straight blade. The myringotome

which is shown in the cut would be a better instrument if the handle and the shank were not quite so long, and with the deflection at the junction of the handle and the shank a right angle. The capsulotome makes a good enough myringotome, and is a capital knife for styes.

Correspondence.

LATIN AS SHE IS WROTE AND SPOKE.

To the Editor of the Medical Record.

SIR: I have read with great interest your editorial in the issue of June 15th, entitled "The Need of a Latin Revival," as well as the many articles which have appeared in the MEDICAL RECORD during the last twenty years, advocating the study and use, by physicians, of the Latin and Greek languages.

It would surely be of great advantage to the medical profession if all its members, both in this country and Europe, could write and speak with elegance both Latin and Greek. All the medical literature of the world could then be printed in one of these classic tongues, and all of it would then be accessible to all of us. Not only at the large international gatherings, where now a Babel of tongues is the most prominent feature, but at the county society, in the rural districts, the musical tones of those languages, which have never been equalled for force, variety of expression, and beauty, would replace the abominable jargon of German, French, Russian, Spanish, English, and "United States."

For the speedy attainment of this ideal condition, let us all devoutly pray, especially those of us who know as yet not a single word of Latin or Greek.

In the meantime—and, as Mark Twain, I believe it was, remarked, "it would probably be a tolerably mean time" for some of us busy old fellows, who would have the duties of a large practice to perform at the same time that we were learning to speak and read and write Latin and Greek—would it not be well to remember that our profession is a practical profession, and that most of us are engaged in the practice of medicine; that many of us are obliged to gain a livelihood for ourselves and our families by that practice, and that life is short and full of duties?

Before we commence in earnest the study of these languages, so necessary to the busy practitioner, will you have the kindness to inform us, through the columns of the RECORD, what has been printed in either of them, during the last five hundred years, that it would pay the physician of to-day to read, if it were translated into his mother-tongue?

A large percentage of the technical terms employed in medicine are of Latin or Greek origin, and of course all prescriptions are written in Latin. This latter statement applies more particularly to the prescriptions of those physicians who are graduates of machine-shops, and whose classical learning and preliminary education was obtained in business offices and in markets, and behind the counters of our large retail establishments.

It is truly gratifying to see the ease with which these gentlemen can express themselves in an unknown tongue; how they can rise superior to the limitations of gender and case, and the facility with which the classic and the vulgar tongues can be mixed, in the prescription, to the great advantage of both. It also has a particularly good effect on the minds of the patient and his friends to read these Latin patois prescriptions. It inspires a proper amount of awe for the great wisdom of the medical mind, and usually prevents the laity, and sometimes other physicians, and even the druggist, from finding out what medicine it is intended shall be given.

No man or woman who has not seen it done can imagine what a simple thing it is for a physician who has never seen a Latin grammar to write out a full Latin prescription. Every doctor knows that the Latin for iron is *ferrum* or *ferri* or *ferra*—it makes little difference which—and the druggist or his youngest clerk knows, as soon as he sees either of these words, that iron in some form is called for, and he immediately puts it up. If the physician writes *rheum* or *rhei* or *rhea*, he knows, and the druggist knows, that it is rhubarb that is called for, and not the celebrated actress of a similar name.

Any druggist knows, if he knows anything, and most of them do, that *aqua* or *aquam* or *aquæ* means water, and that either of these terms can be used in place of either one of the others. If the physician does not know this he ought to. How much better it is to write at the bottom of a prescription, as was done by a physician on a prescription which I saw to-day, "*Cochlear parvum omni tertia hora sumendum*," than it is to write, in the language which most of us are compelled to use in talking to ignorant people, "Take a teaspoonful once in three hours."

It has been asserted, and I presume it is true, that not over five per cent. of the prescription clerks in this State have any knowledge of Latin, and I am acquainted with an ignorant physician who only spent four years in the study of Latin, who makes the absurd claim that it is not safe or scientific for physicians, who have no knowledge of this tongue, to write in it prescriptions to be translated and compounded by druggists who enjoy the advantage of even less learning. As might be expected, this same physician has indorsed the absurd notion that in this country it would be well if all prescriptions were written in plain vulgar "United States." Does not everyone know that mistakes do not occur when prescriptions, containing the names, and methods of preparation, and doses, and frequency of repetition of doses of poisons, are written in Latin patois? Was not this the language of religion and science for many centuries? Does it not resemble the language of Virgil and Cicero and Horace? How, then, can errors occur in writing or translating it, in

this enlightened age? What has been said of Latin applies with equal truth to Greek; they are the languages of science and of scholars, and come perfectly natural to all physicians, either to speak, read, or write, but particularly to write. How much better it would be for our beloved profession in the future, if our young men and maidens, instead of fooling away their time with microscopes and culture-tubes, and bacilli and bacteriological and laboratory work, would return to the true fountain of wisdom, which is the Latin language. How much better to absorb wisdom from these pure sources than to waste time, as many do, in the study of the barbaric language of the stupid Dutchman, a language which contains little that is better than the vaporings of Goethe and Schiller or the pseudo-science of Virchow and Ziemssen. Let us by all means have a "Latin revival," it is without doubt the one thing that is needed in this age to make our profession truly scientific.

Yours truly,

H. L. WALDO, M.D.

Coleridge on Genius and Degeneration.—In the "Letters of Samuel Taylor Coleridge," just published under the editorship of his grandson, Mr. Ernest Hartley Coleridge, the poet gives a curious prolepsis of Lombroso's views as to the intimate connection between genius and disease. The author of "The Ancient Mariner" writes: "It is a theory of mine that virtue and genius are diseases of the hypochondriacal and scrofulous genera, and exist in a peculiar state of the nerves and diseased digestion, analogous to the beautiful diseases that color and variegate certain trees. However, I add by way of comfort, that it is my faith that the virtue and genius produce the disease, not the disease the virtue, etc., though when present it fosters them." Coleridge, as is well known, was a slave of opium. He is said to have swallowed two quarts of laudanum in a week, and on one occasion he took a whole quart in twenty-four hours. He struggled hard for deliverance, and wished that he might be kept from the possibility of indulgence by *force majeure*. In the following passage he sketches out a plan for the "therapeutic seclusion" of narcomaniacs: "This might give occasion for the suggestion of one new charitable institution, under authority of a legislative Act, namely, a Maison de Santé (what do the French call it?) for lunacy and idiocy of the will, in which with the full consent of, or at the direct instance of, the patient himself, and with the concurrence of his friends, such a person under the certificate of a physician might be placed under medical and moral coercion. I am convinced that London would furnish a hundred volunteers in as many days from the ginshops who would swallow their glass of poison in order to get courage to present themselves to the hospital in question; and a similar institution might exist for a higher class of will maniacs or impotents. Had such a house of health been in existence, I know who would have entered himself as a patient some five and twenty years ago." It should not be forgotten that Coleridge spent the last eighteen years of his life under the roof of Mr. James Gillman, a medical practitioner of Highgate, who tended him with more than brotherly care (the expression is Coleridge's own) as an honored and cherished guest, not as a patient in the ordinary sense.—*British Medical Journal.*

Cure of Cancer.—A paper of exciting interest was read by M. Richet at the Académie des Sciences on two cases of cancer cure by sero-therapy. He said that sero-therapy had gained its laurels in the treatment of diphtheria and other affections, and the two cases he brought under the notice of his colleagues at that meeting proved not only that this method can be applied, not only to maladies in which the microbe is known to be virulent, but also in affections like cancer whose microbian origin is still problematic. His experiments were made as follows: On February 9th, M. Reclus removed an osteo-sarcoma of the leg. This tumor was well rubbed up in a mortar with a little water. The liquid was filtered through linen and injected into three animals (an ass and two dogs). This injection was not followed by any reaction, and in five, seven, and fifteen days afterward the blood was drawn and the serum separated. It was this serum that he used in the cases in question. The first of these was that of a woman who had been operated on in October last for tumor presenting the look of a fibro-sarcoma of the size of an orange and adherent to the sixth, seventh, and eighth ribs, without, however, interesting the tegument. In February the tumor returned and rapidly assumed the size of a small orange. The treatment by the serum was commenced on March 12th, and continued during forty days, at the dose of three syringes a day practised around the tumor. From March 25th the tumor commenced to diminish in size, and to-day only a small indurated nodule is found, and the general condition of the patient has improved considerably. The tumor, which was certainly of a cancerous nature, was thus cured by the injections of serum. The second case was that of a man, aged forty-four, who entered the hospital on March 27th last for a tumor in the epigastric region of the size of an orange, and diagnosed cancer of the stomach. Surgical intervention being considered impossible, the treatment by sero-therapy was decided on and commenced on April 6th by a first injection of 4 c.c. (four Pravaz syringes), and from that time up to the 24th of the same month as much as 64 ctm. cubes were injected. A general improvement in the condition of the patient promptly followed; the weight increased by seven pounds, and from April 10th the tumor began to diminish in volume, and at the time of speaking it can be no longer defined by the fingers. In this second case, as in the first, added M. Richet, the improvement was rapid and incontestable, and as regards the first case at least, the anti-cancerous serum did really cure a case of cancer.—*Medical Press.*

Death of the Oldest German Surgeon.—Professor Franz von Ried, the oldest of German surgeons, died at Jena on June 10th, aged eighty-five. He was a pupil of Michael Jaeger, at Erlangen, and lectured in his place for some time. In 1846 he was appointed Professor of Surgery in the University of Jena, and this appointment he held till 1884, when he retired. His principal work was "Die Resectionen von Knochen," (Nüremberg, 1847), which in its day was a leading authority on the subject.

Treatment of Fractured Patella.—The method of Barker is to encircle the patella with a vertical, antero-posterior silk ligature, which, when tied, holds the fragments firmly together. The operation is done subcutaneously, and the ends of the ligature are cut short. —*British Medical Journal.*

SUICIDE IN THE UNITED STATES.

BY JAMES WEIR, JR., M.D.,

OWENSBORO', KY.

THIS paper has been prepared with special reference to suicide as observed in the United States, though voluntary death as found throughout the entire world is, incidentally, discussed therein.

Self-slaughter is of rare occurrence among savage races of people; of so infrequent occurrence, in fact, that one is almost tempted to say that it is unknown among them. This would be, however, a statement not authorized by facts, for savages commit suicide on occasions when influenced by the fear of starvation, or through the dread of a lingering, painful death, or through pride. The higher psychical emotions are wanting in the savage; he is very near, indeed, in this respect, to his pithecoid ancestor, hence he bears the ills of life with all the equanimity of an animal in which æstheticized and idealized *psychos* are absent.

The semi-civilized Chinaman is, on occasions, prone to suicide; and, I am inclined to believe, most of the voluntary deaths occurring among the Chinese are brought about through pride. We know that when overcome in battle entire companies of these people will kill themselves rather than fall into the hands of their enemies. The Chinese are a proud, arrogant, and insular nation. They consider all foreigners as being barbarians and savages, and despise them as beings utterly beneath their notice; hence, when overcome by them, they deliberately slay themselves rather than suffer the ignominy of being slain by these "contemptible and despicable outsiders." The incentive may be, however, the fear of torture. Again, there is a certain standard of virtue that obtains among these people, which makes the fear of rape a powerful factor in engendering the act of suicide in the females of this race. The usages of war among Eastern nations has authorized, heretofore, the violation of all captured females: hence, large numbers of young girls and women kill themselves when they see that they are in danger of being taken by the enemy. This fact was especially noticed during the late war between Japan and China.

The factors inciting suicide in the Chinese and kindred races of people are not those which bring about self-slaughter in those races that are highly civilized: the psychical *materies morbi* are markedly different.

When we turn to the civilized races of the world, statistics show the curious facts that certain ethnic elements enter into the influences predisposing suicide; that voluntary death is largely on the increase; that it follows in the wake of civilization, and that its average is much higher in those races in which are to be found the greatest amount of culture and erudition.

A close study of suicide, as observed in European countries, demonstrates the fact that those nations which have their origin in the Indo-Germanic rootstocks are the most prone to commit voluntary death. With few exceptions, and these exceptions can be readily accounted for by reason of exceptional surroundings, the great centres of suicide, in which the number of suicides per million of inhabitants runs very high, are to be found in Germanic countries.

A glance at the accompanying table, prepared for me by Professor Weidner, of Vienna, for this paper, will at once show this.

TABLE I., SHOWING AVERAGE OF SUICIDES IN VARIOUS STATES OF EUROPE FOR A PERIOD OF FIVE YEARS.[1]

States.	Average Number of Suicides per Million Inhabitants.					General Average.
	1882.	1883.	1884.	1885.	1886.	Five Years.
Austria	125	123	126	129	127	126
Prussia	133	136	130	135	133	133
Hanover	142	144	140	145	143	143
Mecklenburg	168	165	170	173	171	169
Wurtemberg	163	165	162	166	161	163
Saxony	313	311	316	314	317	314
Denmark	260	262	261	260	263	261
Hamburg	305	301	307	309	306	305
France	152	154	153	156	155	154
Spain	20	19	21	18	22	20
Russia	32	35	31	35	36	33
England	68	67	70	72	70	69
Italy	36	35	38	34	39	36

[1] I am inclined to believe that the averages in this table are too low by two or three.—J. W., Jr.

Hovelacque demonstrates that the averages of suicide are decidedly higher in Germanic countries than elsewhere. The following table, which I have slightly modified in order to make it more explicit, appeared in *La Linguistique*, in 1876:

TABLE II. LINGUISTIC TABLE DEMONSTRATING THE PREPONDERANCE OF SUICIDE IN GERMANIC RACES. ADAPTED FROM HOVELACQUE.[2]

Languages.	Maximum Proportion.	Minimum of Suicides.	Average per Million.
People speaking the first group of the Italian languages derived from the Latin (Italians, Spaniards, Roumanians, Portuguese, Corsicans)	74	13	31.5
People speaking the second group of Italian languages, with an infiltration of Celto-Germanic elements (French, Belgian, French Swiss)	260	35	130.0
People speaking Scandinavian, or the first subdivision of the Germanic branch (Danes, Swedes, Norwegians)	268	74	127.8
People speaking the languages derived from the Low German (Frisians, Flemings, Prussians, English, Germans of the North)	301	35	148.0
People speaking languages derived from the High German (Saxons, Central Germans, Bavarians, Austrians, Styrians, Corinthians, German Swiss, etc.)	303	90	165
People speaking the Slavic idioms of the Southeastern branch (Russians, Galicians, Slovens, Croats, Dalmatians)	98	14	40
People speaking the Slavic idioms of the Western branch (Czechs, Moravians, and Poles)	158	98	(130)

[2] Modified from tables used by Morselli in his work on Suicide.

The Celtic and Celto-Latinic races are remarkably free from the desire for self-slaughter. Especially is this true of the former in Ireland, where the average rate of suicide is only about fifteen per million of inhabitants, and of the latter in Spain, where the average is about twenty per million. From data gathered throughout Europe and Great Britain, which embrace a period of time extending from January 1, 1880, to December 31, 1893, I have constructed a table which shows the general averages of the four great divisions of European peoples. I have taken great care to con-

fine my investigations, as far as possible, to cases of authentic suicide, and the following table is based on official records which were furnished by the proper legal officers and persons in authority :

TABLE III., SHOWING SUICIDAL AVERAGES OF THE FOUR GREAT DIVISIONS OF EUROPEAN PEOPLES.

Peoples.	Average per Million.	General Average.
GERMANIC.		
Scandinavians	130	
Germans of the North	155	
Germans of the South	170	116
Anglo-Saxon	75	
Flemings	52	
CELTS; CELTO-LATINS.		
Celts	32	48
Celto-Latins	65	
SLAVS.		
Slavs of the North	45	38
Slavs of the South	32	
URAL-ALTAIC.		
Magyars	52	46
Finns	40	

Morselli observes in his works on suicide that self-slaughter begins in the northern European states with a rather high average, which increases to a maximum in the middle states, and decreases thence slowly to a minimum in the southern states. A study of the tables already presented in this article will show that this observation is true in every respect, although I did not have this in view when compiling them. The general averages of the first table presented will show that there was an increase in the number of suicides per million in nearly all of the states cited ; if the data had embraced a longer period of time, this increase would have been shown clearly and emphatically in all of the States. Wherever records have been kept for any number of years they always show an increase of suicide. In Sweden, where records of the disease have been kept for a long time, statistics show that there has been an increase per million of 3 or 4 for every decade. In 1860, the average for the United States was 32; in 1893, it was 55 for each million of inhabitants; Ireland has crept up from 10 per million in 1841 to 15 per million in 1893. The average in England, in 1886, was 70 (69 +) per million of inhabitants ; in 1893 it was 76 per million ; in Switzerland, in 1872, it was 196, in 1893 it was 204 ; in Italy, in 1886, it was 36, in 1893 it was 42 ; in Russia, in 1886, it was 33, in 1893 it was 40. Two groups of periods of five years each, taken from records obtained throughout the United States, from Maine to Texas, and from New York to California, show that there is an increase in suicide in every section of the country. I do not propose to burden the reader's attention with heavy loads of official figures, therefore will make one group answer for all in establishing the fact. The following table was furnished me by Dr. L. J. Mitchell, of Chicago, medical assistant to the coroner of Cook County, Ill.

TABLE IV., SHOWING INCREASE IN SUICIDE PER MILLION INHABITANTS IN CHICAGO AND COOK COUNTY.

Years.	Male.	Female.	Total.	Per Million.
1890	173	43	216	144
1891	200	70	270	148
1892	228	66	274	150
1893	282	83	365	182
1894	260	57	317	158
Gen'l Average per year	228.4	63.4	288.2	156.2

This table shows an increase of 12 per million of inhabitants in a period of five years. This large increase is undoubtedly due to the influence of the Centennial year (1893), when the high average of 182 per million of inhabitants was reached ; leaving out this year, an annual increase of 5 or 6 will be observed, which is, probably, the natural ratio of increase for this section of the country. There are exceptional influences at work in Chicago which create this high rate of increase, and these adjuvants to this increased average (per million of inhabitants) of suicide will be discussed elsewhere in this paper. In Central Pennsylvania and Southern Ohio the average rate of increase is about the same. In Hamilton County, O. (Cincinnati), the number of suicides in 1894 was 87, an annual increase of 3.0 in five years per million of inhabitants, while in Central Pennsylvania the increase per million was 3.1.

In the Northwestern States an annual increase of four per million, for a period embraced by the last five years, can be noticed. The general average of annual increase for the United States during the period embraced by the last five years is 1.5, consequently there must be some factor at work which engenders the high averages in the localities just cited. That factor is, undoubtedly, the Germanic element (Danes, Swedes, Germans, etc.), which has been injected into the populations of those sections where these high averages of increase prevail.

The preponderance of suicides of Germanic extraction can be noticed, locally, throughout the entire United States ; in fact, if it were not for these peoples, I am confident that the general average for the United States would fall far below its present mark. In a population composed equally of Germans and Americans the rate of suicide is eighty-five per cent. German, and this rate does not vary throughout the entire United States.

Let us turn aside for a moment and discuss the question : Why does suicide preponderate among the Germanic peoples ? I do not propose to treat this subject in this paper with the fulness and detail that it really deserves, for that would be impossible in the short space of a magazine article ; therefore I will only enter into it incidentally. The coroner of Cook County, Ill. (Chicago), in his last report writes as follows : "The fact of this practice among the German race in a measure helps to bear out the theory advanced by some members of the medical profession, that the continued consumption of beer and ale is more conducive to low spirits than is that of whiskey, especially when the fact is taken into consideration that among all the Irish population of the city only ten committed suicide during the past twelve months. The Irishman, it is safe to assume, drinks whiskey in the same proportion that his German brother consumes beer."

The idea that beer-drinking is the cause of the preponderance of suicide among Germanic peoples is one that is popularly accepted throughout the United States ; it is, however, in my opinion, erroneous and based on faulty logic. The logician who deduces a cause from a sequence is standing on a precarious foundation ; he bases his premises on an assumption—a weak and superficial basis in logicial reasoning. The English race (Anglo-Saxon) is a branch of the great Germanic race and is a beer-drinking (ale, porter, half-and-half, etc.) people, yet the average rate of suicide is, comparatively speaking, not at all high. Alcohol in any form is, undoubtedly, a factor in producing degeneration, and suicide is, emphatically, an evidence of degeneration ; hence, I am inclined to believe that, if alcohol were the exciting cause, whiskey-drinkers would more readily succumb to suicidal desire than beer-drinkers. A careful analysis of pure malted liquors will show that they contain no ingredient capable of causing cerebral degeneration save alcohol. It is true that lupulin is toxic, but the quantity imbibed in pure beers is not sufficient, in my opinion, to occasion any great amount of degeneration. The cause of this preponderance of suicide in Germanic peoples is not occasioned by any indulgence of the appetite, but has its origin in a psychical trait inherent in the race. As far back as history goes, both written and legend-

ary, the Germanic races have shown a strange indifference to death. They are not braver than many other races, yet they do not seem to value life as highly as do the Celts and Celto-Latins. When the balance-wheel of *psychos* loses its equipoise through degeneration, this indifference to death becomes a strong desire for death, and the German suicides; this, in my opinion, is the true cause of the high suicidal averages of the Germanic races. Let us return now to the averages of increase as observed in the United States. The condensation of populations in circumscribed areas, viz., in cities and large towns, is a potent factor in building up increased averages of suicide. This we can readily observe by a study of mortuary statistics (suicide) as furnished by the coroners' reports emanating from all of the large cities and towns of the country. Thus, the average annual rate of increase, per million of inhabitants, for the State of New York is about 1.2, while the rate of increase for New York City is at least 4.0. These rates are calculated from the reports of the last ten years, and mean that every five years adds an average of four per million of inhabitants to the annual number of suicides occurring in New York City, and one per million of inhabitants to the number occurring in the State at large. In Chicago, as I have shown elsewhere, the rate of increase, per period of five years, is annually 6.0 per million of inhabitants. This large increase is undoubtedly due to two factors: the first is the phenomenal growth in population of Chicago during the last five years; the second is the large influx of Germanic peoples within her borders. Lansing, Mich., with a population of 20,000, has an average of 3 suicides annually; this gives a rate of 150 suicides per million of inhabitants. The annual increase for the entire State of Michigan, for a period of five years, is between 3.0 and 4.0; and it is the same in Wisconsin and Minnesota.

These high averages are not to be observed in any of the Eastern States, especially in those States of the seaboard. It is true that the general average of New York State is rather high (98), but this is due to the influence of condensation of population in Brooklyn, New York City, and other large towns of the State. The general average of the State of Pennsylvania is 92; this comparatively high average is undoubtedly due to the Germanic elements which enter so largely into its population. In Maine, Vermont, and New Hampshire the general average, deduced from official records, is about thirty-eight per million of inhabitants. This average gradually decreases in the States forming the Atlantic seaboard, with the exception of the States of New York, Pennsylvania, Massachusetts, Rhode Island, and New Jersey toward the south, until it reaches the low average of 30 per million of inhabitants in Georgia and Florida. In the Southern, Middle, and Western States the averages run from thirty to sixty, being higher in the Middle and Western States than in the Southern. When we stop and consider that in the United States alone over four thousand people annually commit self-slaughter, and that every five years will see a material increase in this already large number, we stand amazed. Yet I have not exaggerated the estimate in the slightest degree. If I were to write down the total sum of all the people who annually make way with themselves, blank amazement, and perhaps absolute incredulity, would fill the minds of nine-tenths of those who read this article. To those who are at all curious, this problem—*i.e.*, the total annual number of suicides in the civilized world—is one which can be easily solved. Table III. gives the general averages for the European nations, including Great Britain; to these add the general averages for the United States (55), Mexico, Central, and South America (38), and Australia (65); divide the sum of these numbers by the number of averages and this will give, approximately, the general average, per million of inhabitants, for the entire civilized population of the world.

In the United States suicide begins at a very early age. During the past ten years almost a thousand boys and girls below the age of sixteen years have taken their own lives. In New York alone, from 1871 to the year 1876, thirty-four boys and girls committed suicide, and five of the thirty-four were between ten and fifteen years old. The records of Philadelphia, barring a slight increase due to condensation of population, show the correct proportion of child suicides.

TABLE V., SHOWING GENERAL AVERAGES OF SUICIDE IN PHILADELPHIA, PA.—MEN, WOMEN, AND CHILDREN—FOR A PERIOD OF TEN YEARS.[1]

Years.	Males.	Females.	Total.	Boys.	Girls.	Total.
1884	72	17	89	1	..	1
1885	62	16	78	2	2	4

1893	100	18	118	..	..	..
General average			95	General average		2

[1] Furnished by M. V. Ball, Medical Department, Eastern State Penitentiary, Philadelphia, Pa.

In this county (Daviess County, Ky.) two children have committed voluntary death in the past fifteen years—one, a boy, by hanging; the other, a girl, by poison. When I take into consideration the extraordinary precocity of the juvenile portion of the populations of our large cities, I wonder that the number of child suicides is not much larger. Age undoubtedly acts as a factor in increasing or decreasing the number of those who commit self-slaughter, certain favorable ages preponderating in all the lists of suicides in my possession. From two lists of voluntary deaths, of a thousand each, taken from two periods of five years each, viz., 1882–86 and 1889–93, and from sixteen States, I have constructed the following tables:

TABLE VI., SHOWING THE INFLUENCE OF AGE ON SUICIDE.

1882-86.	Male.	Female.
Age under 10 years	..	1
Age under 15 years	1	2
Age between 15 and 20 years	10	140
Age between 20 and 30 years	125	260
Age between 30 and 40 years	364	97
Totals	500	500
1889-93.		
Age under 10 years	..	..
Age under 15 years	..	4
Age between 15 and 20 years	8	135
Age between 20 and 30 years	130	290
Age between 30 and 40 years	362	71
Totals	500	500

It will be at once observed that the most favorable age for self-slaughter in women is between the ages of twenty and thirty years, and that in men the favorable age is between thirty and forty. In the next table of 1,000 suicides, 500 men and 500 women, the minimum age was twenty and the maximum age eighty years.

TABLE VII., SHOWING THE INFLUENCE OF AGE ON SUICIDE.

1890-94.	Male.	Female.
Age between 20 and 30 years	110	205
Age between 30 and 40 years	203	115
Age between 40 and 50 years	102	92
Age between 50 and 60 years	56	60
Age between 60 and 70 years	19	21
Age between 70 and 80 years	10	7
Totals	500	500

It will be observed that the same law holds good in this table also; the favorable age for woman lies between twenty and thirty years, and that for man be-

tween thirty and forty years. There is a gradual decrease in the number of suicides in women after the age of thirty, and in men after the age of forty, years.

Certain months of the year as well as certain hours of the day appear to be selected more frequently by persons committing voluntary death than others. Thus, there are more suicides in the months of July, August, and September than in other months, and more people commit self-slaughter between the hours of 11 A.M. and 12 M. than at any other hour during the day. It is comparatively easy to assign a physiological reason for the preponderance of suicide during the above-mentioned months, for it is a well-established fact that the hot, sultry weather of our summers acts very deleteriously on our nervous systems. It is not so easy, however, to assign a reason for the preponderance of suicide between the hours of 11 A.M. and 12 M. That this is a fact, however, a study of the following table will clearly demonstrate :

TABLE VIII., GIVING HOUR OF SUICIDE IN 1,986 CASES.

Hour.	Cases.	Hour.	Cases.
6 A.M.	95	6 P.M.	75
7 "	90	7 "	73
8 "	102	8 "	90
9 "	110	9 "	68
10 "	108	10 "	65
11 "	120	11 "	50
12 M. (noon)	136	12 midnight	55
1 P.M.	82	1 A.M.	51
2 "	101	2 "	49
3 "	106	3 "	46
4 "	75	4 "	75
5 "	78	5 "	66
Total	1,203	Total	783

It will be seen also by this table that the suicides committed during the day largely outnumber those committed during the night ; all of my lists declare this to be a fact.

Baly and Boudin make the extraordinary statement that the negro evinces a great predilection for suicide. This is contrary to the proposition advanced in the first part of this paper, *i.e.*, that suicide is of infrequent occurrence among savages.

I am not aware of the source from which MM. Baly and Boudin derive their information, but, be it whatever it may, it is wholly at variance with the statistics in my possession. We might safely assume on general principles, even if there were no records in existence, that the statement of these gentlemen is erroneous ; for we know that the negro in the United States is descended from ancestors who, two hundred years ago, were utter savages, and, since it is an accepted and well-established law that suicide follows in the wake of high civilization and coincident intellectuality, it is reasonable to assume that the pure-blooded negro has not reached that degree of psychical development which must accrue ere the desire for voluntary death is engendered. The pure-blooded negro is remarkably free from those forms of insanity which make themselves evident by vagaries of the higher emotions ; in point of fact, he is an individual who does not possess the high psychical development of the civilized white. Says Romanes, one of the most distinguished psychologists in the world, as well as one of the profoundest thinkers : "The psychology of uncivilized man shows, in a marked degree, a kind of *vis inertiæ* as regards any higher development. Even so highly a developed type of mind as that of the negro—submitted, too, as it has been in millions of individual cases, to close contact with minds of the most progressive type, and enjoying, as it has in many thousands of individual cases, all the advantages of liberal education—has never, so far as I can ascertain, executed one single stroke of original work in any single department of intellectual activity."

When we turn to actual evidence, we find that these psychological reasons for the non-prevalence of suicide among negroes are corroborated in every respect.

In Georgia, Alabama, Louisiana, Mississippi, North Carolina, South Carolina, Tennessee, and Virginia, where the negro is greatly *en évidence*, the average rate of suicide for the pure-blooded negro is only one in every hundred of suicides. This average, in all probability, is a little too high, but owing to the lack of detail in the vital statistics of these States, it is a conservative one, and as near the actual rate as possible under the circumstances. The half-breed negro is, however, almost invariably a degenerate individual, having inherited all of the weak physical and psychical traits of his white ancestor ; consequently the rate of suicides for mulattoes, quadroons, and octoroons is, comparatively speaking, rather high. The pure-blooded negro, like any other savage, will commit suicide on occasions, but these occasions are rare, indeed, and are brought about by the most exceptional circumstances.

The methods by which or through which people in the United States commonly commit suicide are hanging, shooting, drowning, poisoning, producing hemorrhage, and asphyxiation. The proportion in which these methods are used throughout the United States is shown, approximately, by the following table :

TABLE IX., SHOWING THE METHOD COMMONLY USED TO PROCURE VOLUNTARY DEATH IN THE CITY OF MILWAUKEE, WIS.; YEAR 1894.[1]

Method Used.	Cases.	Males.	Females.	Average per Million Inhabitants.
Hanging	20			
Shooting	10			
Drowning	4			
Poisoning	10	X.	X.	X.
Cutting Arteries	2			
Cutting Throat	4			
Illuminating Gas	3			
Total	53	46	7	150

[1] Furnished by Henry Ott, coroner, Milwaukee County.

Suicide by inhaling illuminating gas is greatly on the increase in the Eastern and Middle States. Says Dr. Francis Harris, medical examiner for Suffolk County (Boston), Mass., in a letter to me : "I should add, in regard to the matter of methods, that suicide by illuminating gas is rapidly increasing in this State. The ease and painlessness of the method, as well as the leaving the cause always a matter of doubt as between accident and suicide, have made this method popular."

I have asserted that suicide is most frequent in those nations or communities where erudition, coincidently, civilization, is highest. We have seen that this is a fact in the countries of the Old World ; now let us see if this fact obtains in the United States.

In newly settled regions of this country, say, in the Western States, erudition is far below par, and civilization is rude and unconventional. In these States, the average rate of suicide, per million of inhabitants, is far below that of the much older Eastern States. For purposes of comparison, I will take the States of Colorado and Massachusetts. During the last thirteen years, there have occurred in Colorado (population, 300,000) 102 suicides, an annual average of 28+ per million of inhabitants. In Massachusetts, where erudition is higher, probably, than in any other State of the Union, and where the population is uninfluenced to any extent by Germanic elements, the annual rate, per million of inhabitants reaches the high average of 98+. The following table brings out this fact very patently :

TABLE X., SHOWING NUMBER OF SUICIDES IN THE STATE OF MASSACHUSETTS FOR THE PERIOD OF TIME EMBRACED BY THE LAST FIVE YEARS, 1889-1893.[2]

Year.	Estimated Population.	Male.	Female.	Total.	Per Million Inhabitants.
1889	2,175,153	157	42	199	Approximation, 91
1890	2,238,943	156	40	196	" 87
1891	2,303,536	142	45	187	" 81
1892	2,369,994	211	62	273	" 115
1893	2,438,363	228	62	290	" 119
Total		894	251	1,145	Gen'l averages, 98+

[2] Furnished by Francis A. Harris, M. D., Medical Examiner, Suffolk County, Mass.

Of course, condensation of population must be considered as one of the factors in the production of this high average (98 +), yet, even when we allow for this, we will still have an average far above that of Colorado (28 +).

BLOOD ABSORPTION FROM THE PERITONEAL CAVITY.

By F. H. SOUTHGATE, M.D.,

CINCINNATI, O.

ASSISTANT TO THE CHAIR OF PHYSIOLOGY, MEDICAL COLLEGE OF OHIO.

Almost all the injections of blood into the abdominal cavity for the study of absorption have been made solely with reference to the ordinary study of the transfusion of blood. The present researches deal specifically with the effects of this transfusion upon the blood, and upon the circulation of the animal. Recklinghausen, after the intraperitoneal injection of defibrinated blood, perceived an active filling of the lymphatic vessels on the pleural surface of the diaphragm with the same. Ponfick, on introducing defibrinated blood into the abdominal cavity, found that its absorption is accompanied by an increase in the number of blood-corpuscles in the blood of the rabbit so treated, an increase which reaches its maximum on the first or second day after the transfusion. Further than this the above-referred-to researches need not be taken into account.

The following experiments were made, first, to observe the effect of blood absorption upon the animal and to determine the condition of the reabsorbed blood on its return to the blood-vessels; second, to discover the effect of an auto-transfusion on the number of blood-corpuscles in the blood. The experiments are set forth in the following order: I. The direct transfusion of blood from the carotid artery of another animal of the same species. II. The simple removal of blood from the carotid artery. III. The direct auto-transfusion of blood from the carotid artery to the peritoneal cavity. IV. The direct transfusion of blood from the carotid artery of another animal of a different species.

For the last experiment the blood of a dog was taken; the other animals were all rabbits of the same species, weighing between 1,500 and 2,000 gm. each. As an instrument for measuring the amount of blood transfused, a Ludwig's Stromuhr was selected. This instrument was connected with a rubber tube, extending from the carotid cannula of the one animal to a small glass tube inserted in a minute incision in the abdominal wall of the other.

In order to determine whether the blood, when reabsorbed, returns to the blood-vessels without having undergone any serious impairment, calculations were made of the number of red corpuscles in the blood of the animal before the transfusion, and at various periods of time thereafter. A count was also made of the number of red blood-corpuscles in the blood of the rabbits suffering from simple hemorrhage, and of those in the blood of the rabbits which had received the foreign blood (that of the dog), on account of the well-known power of the latter to produce hæmoglobinuria when injected directly into the vessels of a rabbit.

The count of the red blood-corpuscles was, at first, made with a Zeiss-Thoma apparatus, but owing to the number of observations necessary to obtain an available average, and the time requisite for this purpose, as well as that consumed in the other operations on the animals, this method was found to be inferior, as a means of comparison, to the Blix-Hedin-Gärtner Hämatokrit method, as improved by Dr. Cowl, a full explanation of which will be found as an addenda to this paper. By this method three or four observations were made at each of the periods above mentioned, both before and at stated intervals after transfusion. These observations show a remarkable uniformity, far exceeding that to be obtained, with ordinary care, by the counting method of Zeiss. The extreme variation from the average in each set of observations was, in no instance, more than eight per cent. of the number of blood-corpuscles indicated by that average, while the average variation between the two extreme observations was only 1.5 per cent.

The specimens of blood were taken from the subcutaneous abdominal veins in preference to the ear, as the results were more regular, and the rabbits were kept on the board only as long as the primary operations lasted.

I. The Transfusion of Blood from Another Animal.—In these cases, as well as in the following ones of auto-transfusion, three hours after the transfusion found the pleural surfaces of the diaphragm (described by Recklinghausen, Ludwig, and others) beautifully injected and oftentimes distended with blood. In general these lymphatic vessels ran directly across the muscular fibres, instead of with them like the veins, and coming from both sides of the sternum they united into a stem, which, running forward, evidently emptied into the lymphatic trunks accompanying the mammary vessels. Neither upon the peritoneal surface of the diaphragm nor in the abdominal cavity were injected lymphatic vessels to be found.

After the transfusion the rabbits showed the following appearances: In all cases, at the end of the first hour, there was distention of the veins. In two cases the ears and mucous membranes assumed a bluish color. One case developed a marked protrusion of the eyeballs. The blood-pressure was observed in seven cases. In four cases it rose, in three there was a slight fall. At the end of first, second, and third hours after the transfusion, observation showed that the average increases in the number of corpuscles in the blood stood at ten, eleven, and four per cent. respectively.

In three of the cases urine was not passed during the research, and only a few cubic centimetres were found in the bladder after death. In one case 16 c.c. were passed forty-five minutes after the transfusion; in a second case 10 c.c. were passed in twenty minutes thereafter. In none of these cases was there evidence of hæmoglobinuria. In another case 42 c.c. of blood were transfused into the abdominal cavity of a rabbit weighing 2,000 gm. The blood changes pursued the typical course described above. The rabbit was kept under observation for ninety-six hours, being cared for in the same manner as before the observation, and it remained perfectly well.

II. Simple Hemorrhage from the Carotid Artery.—In six cases of simple hemorrhage, with an average loss of 27 c.c. of blood, there was an average reduction of twenty-three per cent. in the number of corpuscles at the end of one hour after the abstraction of the blood, and at the end of the second hour this average had increased to 31.5 per cent. of the original number of corpuscles.

III. The Transfusion of Blood from the Carotid Artery into the Peritoneal Cavity of the Same Animal.—The three cases of auto-transfusion, owing to their progressive nature, deserve detailed consideration. Twenty-four, and 30 c.c. of blood, respectively, were abstracted from the three carotids; 1, 2, and 11 c.c. of blood lay unabsorbed on the section in the peritoneal cavity three hours after the operations. In each case 9 c.c., which remained in the transfusion apparatus, were lost to the animal. This shows an absorption into the peritoneal cavity of 14, 12, and 11 c.c., respectively. We may note here a markedly greater reabsorption in the cases of lesser hemorrhage. Although a difference of 6 c.c. between the amounts of hemorrhage is absolutely small, it is relatively great when superimposed upon a loss of 24 c.c. of blood taken

from rabbits weighing from 1,600 to 1,800 gm., and in these cases this difference is more clearly set forth by the changes in the number of blood-corpuscles in the blood of the animals, resulting from the auto-transfusion. Then, too, it is seldom that more than 40 c.c. of blood can be drawn from the carotid artery of an animal of such weight without causing death.

Professor Gad informs me that he is convinced, by former researches of his own respecting the auto-transfusion of a small amount of blood (about fifteen cubic centimetres in the medium-sized rabbit), that a perfect reabsorption is accomplished within three hours, at the end of which time not a particle of waste matter is to be found in the peritoneal cavity, and there is no trace of the distended lymphatic vessels of the diaphragm.

According to Wegner, if a large amount of artificially warmed serum (not more than 12 per cent. of the weight of the body) be introduced into the abdominal cavity of a rabbit, only two-thirds, or still less, of the whole amount will be found in the peritoneal cavity of the animal an hour after it has been killed. After the transfusion of an amount of the same fluid (about five per cent. of the weight of the body) into the abdominal cavity of a dog, only one-fourth was reabsorbed.

The effect of the loss of blood after the auto-transfusion is shown in the diminution of the number of blood-corpuscles, for in the three cases, with a loss of 19 c.c. and a reabsorption of 11 c.c., the number of blood-corpuscles showed, at the end of the first hour, a diminution of 27 per cent., and at the end of the second hour a diminution of 24 per cent.

Whereas, in the first case, with a reabsorption of 14 c.c. of blood and a loss to the animal of 10 c.c., the number of blood-corpuscles at the end of the first hour after the operation had not diminished, and at the end of two hours the corpuscles showed a diminution of 5 per cent.; in the second case, with a reabsorption of 12 c.c. and a loss of 12 c.c., there was, at the end of the first hour, a diminution of 10 per cent., and at the end of the second hour the blood-corpuscles had increased to the original number; and in the third case, with a regain of 11 c.c. by reabsorption and a loss of 19 c.c., there was at the end of the first hour a diminution in the number of corpuscles amounting to 27 per cent., while at the end of the second hour the amount of diminution had decreased to 24 per cent. For extraneous reasons, auto-transfusion was not carried out in a large number of cases. In order to make a comparison with the cases of simple hemorrhage, we leave out of account these individual differences, which evidently result from the complicating hemorrhage, and take an average. We find that whereas in simple hemorrhage, as above stated, the number of blood-corpuscles is reduced, at the end of the first and second hours, 23 and 31.5 per cent. respectively, after auto-transfusion, with more or less loss of blood to the animal, the reduction at the end of the same periods of time is but 13.5 and 12 per cent. respectively.

IV. The Direct Transfusion of Foreign Blood.—In one case an easy estimate of the destructive effect of foreign blood, especially concerning the formation of hæmoglobinuria, was made. Twenty cubic centimetres of blood were taken directly from the carotid artery of a healthy dog and injected into the peritoneal cavity of a sound rabbit, with the following result: After an hour hæmoglobinæmia was discovered in the plasma, by means of the guaiacum test, and the red color of the blood, together with the absence of the corpuscles, as demonstrated by the use of the microscope, proved the presence of free hæmoglobin in the blood. A small amount of urine was found in the bladder two hours after the transfusion. This, closely resembling the blood in color, showed itself to contain hæmoglobin, but no blood-corpuscles. Urine passed during the night contained no hæmoglobin. The animal was not allowed food after the operation until the second night. On the post-mortem examination a mass of dark-red fluid (about a cubic centimetre) was found on the pericardium, the pleura, and the peritoneum.

From the foregoing researches the following points were noted:

1. Direct transfusion of arterial blood from one animal to the peritoneal cavity of another animal of the same species causes no perceptible injury to the animal receiving the blood.

2. Homogeneous, non-defibrinated blood is quickly reabsorbed from the peritoneal cavity and this absorption takes place chiefly through the diaphragmatic lymphatics, and these lymphatics, as a rule, do not communicate with the thoracic duct.

3. Homogeneous blood reabsorbed from the abdominal cavity does not produce hæmoglobinuria, but seems to be absorbed and to circulate as normal blood.

4. After a moderate loss of blood absorption from the abdominal cavity takes place quickly, but the greater the loss of blood the slower the absorption.

5. After simple hemorrhage the relative quantity of the solid elements of the blood is diminished.

6. After hemorrhage, if there be sufficient compensation by transfusion into the peritoneal cavity, the general circulation changes very little or not at all.

7. Simple intraperitoneal transfusion of blood enriches the blood of the animal receiving it, and the increase in the corpuscular elements reaches its maximum within three hours.

8. Transfusion of foreign or heterogeneous blood into the abdominal cavities of rabbits produces hæmoglobinuria and results in the death of the animals.

For the incitation to the above researches, as well as for assistance in pursuing the same, I wish to express my sincere thanks to Professor J. Gad, in whose laboratory, by his courtesy, they were carried out. I am also much indebted to Dr. W. Y. Cowl for his advice and friendly assistance.

IMPROVED MEANS FOR THE HÆMATOCRIT METHOD OF BLOOD EXAMINATION.[1]

By W. Y. COWL, M.D.,

CINCINNATI, O.

THE simple and rapidly executed method of determining in a minute specimen of blood the relative proportion of corpuscles to plasma by means of centrifugal force, which was devised and first employed by Blix in 1885, and since then further pursued and improved by Hedin, Daland, and Gaertner, has lately been condemned by Bleibtreu and also by Biernacki, upon the ground of comparative determinations with two other methods for ascertaining the amount of corpuscles in larger quantities of blood.

That of the former investigator is of a chemical character and consists in the determination, first, of the amount of combined nitrogen and therefore of albumin in the supernatant fluid from each of two portions of the same specimen of defibrinated blood some hours after dilution with a physiological salt solution (sodium chloride, 6 to water 1,000) to a different known degree in the case of each portion, and thence, by calculation, the amount of serum and consequently of corpuscles in the original specimen.

The method is based upon a long-known and well-established procedure devised by Hoppe-Seyler, and consisting in determinations of, 1, the amount of oxyhæmoglobin and albumin in the blood as a whole; 2, the amount of the same in the blood-corpuscles alone; 3, the amount of fibrin; 4, the amount of albuminous matter in the serum, and, 5, by calculation from these

[1] A communication with demonstration given at the meeting of German naturalists and physicians, Vienna, September, 1894, detailing researches carried out at the Physiological Institute of the University of Berlin.

data, the amounts of serum, of plasma, and of blood-corpuscles in the original specimen.

Biernacki, on the other hand, simply measures the compact mass of corpuscles after complete sedimentation from the plasma or serum. Both of these methods require a considerable quantity of blood, which, in the case of the first described, varies inversely with the duration of the sedimentation requisite for yielding sufficient serum for an accurate application of Kjeldahl's method for determining the amount of nitrogen present.

Bleibtreu's procedure has been criticised, however, upon the ground of experiments by Hamburger and by Biernacki. In the hands of the latter, nevertheless, as in Bleibtreu's original research, it has yielded more constant results than the hæmatocrit method as hitherto employed.

Biernacki's method, which possesses a like advantage, requires two to three days of sedimentation, and occasions a shrinkage of the red blood-corpuscles, which he attributes to the extrusion of plasma previously held dissolved or suspended within them.

Both of the described methods, however, have yielded figures which agree more or less closely with those long since obtained by Welcker and others for the average relative quantities of plasma (sixty-four per cent.) and of erythrocytes (thirty-six per cent.) in normal blood after defibrination, by means of calculations from average microscopic measurements of the red disks and from determinations of the average number of the same in a certain volume of blood.

The various percentages obtained for the amount of corpuscles in normal blood by the hæmatocrit method in the researches hitherto published are, on the other hand, largely in excess of those of Welcker as well as of Bleibtreu and of Biernacki. Both of the latter experimenters, furthermore, on direct comparison of the hæmatocrit with their own methods, with various kinds of blood, find that the percentages in a series of different specimens lie not only widely apart, but do not run parallel. These facts alone lead each author without further ado to express the wish that the hæmatocrit method disappear from use.

Such a summary disposal of the matter, however, seems to us quite unjustified, so long as they have not found the source of apparent error, and especially so in view of the questionability of their own methods on the one hand and the great and evident advantages of the hæmatocrit method of blood examination on the other, namely, the simplicity and directness of the process, the minute quantity of blood required for examination, the avoidance of calculation, and particularly of multiplication, in attaining the result, and the brief period of time requisite for its performance.

The need of a method possessing such advantages came home to us personally at the beginning of a series of researches on the Absorption of Blood from the Peritoneal Cavity, undertaken at the instance of Professor John Gad, under my supervision, by Dr. F. H. Southgate, of Newport, Ky., carried out at the Physiological Institute of the Berlin University during the past semester. In this investigation observations of changes in the corpuscular richness of the blood in animals before and after operation were requisite in such number as to practically exclude the employment of any of the above-mentioned methods or indeed of the hæmatocytometer of Thoma and Zeiss.

We have therefore subjected the hæmatocrit method to a critical examination, to the results of which we here call attention. Before doing so, however, we would make a prime distinction between the different methods of blood examination already mentioned which has not been noted by previous investigators, but which is necessary owing to facts that point to a changeability of the red blood-corpuscle in volume ; namely, as found by Biernacki, it shrinks when at rest in its own plasma or serum ; furthermore by Lackschewitz, that it swells within or without the organism when the plasma is thinned, even with physiological salt solution ; again, as found in my own researches, its size depends within wide limits upon the concentration and chemical character of the solution added to the blood. It is thus evident that those methods which, like Hoppe-Seyler's and Bleibtreu's, determine the amount of a certain inherent substance in weight must be kept separate from those like the hæmatocrit and Biernacki's method, which determine the volume of the corpuscles as a whole. The former, supposing them to be intrinsically worthy of it, are to be given the preference for researches in which absolute percentages are requisite, while the latter, by reason of their simplicity or rapidly completed execution, afford a means for many equally important scientific investigations, as well as clinical examinations, that would otherwise be impossible ; the determinations in these latter cases being relative instead of absolute, but *a priori* no less exact ; the precision, which depends on uniformity of procedure in making the determinations being not less binding in the one case than in the other.

That examinations with reference to either the volume or weight of the corpuscles of the blood as a whole cannot be entirely exact at the present time may furthermore be readily maintained by reason of the hitherto disregarded volume or weight of the fugitive corpuscles, usually denominated blood-placques, which have been long since demonstrated by Norris to be present in large numbers in every specimen of normal blood, although disintegrating to a large extent soon after the latter is shed.

In a preliminary examination of the hæmatocrit method as hitherto employed we have found that a serious source of error lies, in point of fact, in the substance employed to prevent coagulation—namely, potassium dichromate, either as contained in a simple two and a half per cent. solution of the salt or in Miller's fluid, potassium dichromate, 1 ; sodium sulphate, 2 ; aqua, 100.

Upon microscopic examination of a number of specimens of corpuscles removed by centrifugal force from a mixture of blood with either of these solutions we have observed a granular organic sediment, at times in patches, enclosing a number of red disks. From this it is apparent that the bichromate solution may vitiate the result by a precipitation or coagulation of solid matter from the plasma, thus increasing the apparent amount of corpuscles in the specimen subjected to examination.

It could be questioned, in the cases mentioned, whether the adventitious sediment might not be referred to the centrifugation alone, and to this doubt we were led by observing that blood freshly drawn without any admixture will coagulate throughout within a few seconds, when subjected to strong centrifugal force, which would otherwise remain fluid for over four minutes. On simply mixing blood and the bichromate solution, however, the same either takes on a uniform opacity of greenish-black hue or throws down a slowly sinking voluminous organic sediment, according to the proportion of the two ingredients. This is true of admixtures with all solutions of potassium dichromate of a strength available for the hæmatocrit process.

Owing to the well-known destructive action on the blood of potassium salts in general, in contradistinction to those of sodium, it is remarkable that the sodium salt has not been proposed nor tested for the hæmatocrit process. We have, therefore, made comparative tests of potassium and sodium dichromate in simple solution of various strength,[1] and find fundamental differences in their action in conformity with

[1] Owing to the presence of two molecules of water of crystallization in the sodium compound, absent in that of potassium, their molecular weights do not vary more than one and four-tenths per cent., hence the strengths of the solutions are almost the same, whether measured by the absolute weight or the chemical equivalence of the contained salt

the fact just mentioned. Whereas solutions of the potassium salt, in strengths stronger than two and a half per cent., mixed with normal blood, occasioned such a precipitation or coagulation as to yield on centrifugation a column of solid matter, equal in bulk to the entire mass of blood, those of the sodium salt, even in a strength of five per cent., produced no such coagulation in the plasma. Furthermore, whereas a one per cent. solution of potassium bichromate would dissolve the entire mass of red blood-corpuscles in the same manner as distilled water, the same strength of the sodium salt would not destroy them, although dissolving out hæmoglobin in some measure.

Again, while both salts in weak yet somewhat stronger solution (potassium bichromate, 1.5 and 2.0 per cent.; sodium bichromate, 1.0 and 1.5 per cent.) occasion a perceptible precipitation of albumin noticeable in the cloudiness of the fluid after removal of corpuscles by centrifugation, the amount of this precipitation is uniformly greater in the case of the potassium than of the sodium dichromate, as the following percentages of corpuscles plus precipitated albumin in the same blood after centrifugation with solutions containing 1.0, 1.5, 2.0, and 2.5 per cent. respectively of each salt indicate, namely, with potassium bichromate, ninety-eight, eighty, sixty-seven, and fifty-seven per cent.; with sodium bichromate, sixty-seven, sixty-three, sixty-one, and fifty-three per cent.

The larger figures are certainly in part due to swelling of the corpuscles, which may be observed under the microscope; weak solutions, furthermore, do not prevent coagulation, which, although the rapid removal of the corpuscles from the plasma prevents clotting in the mass of the latter, may take place between the corpuscles themselves and thus hinder complete compression.

As has long been known, the solution of the red disks by distilled water, above referred to, may be avoided on diluting blood by employing a solution of common salt in a strength approaching that of the blood plasma in this constituent (7.3 per 1,000), such as is commonly known as physiological salt solution. When blood, however, is removed from the blood-vessels, defibrinated and diluted with a salt solution of exactly this strength, and then allowed to deposit its corpuscles, it will soon be perceived, in most cases, by the color of the supernatant serum, that hæmoglobin has become dissolved in the solution. This, as has likewise long been known, may usually be prevented by employing somewhat stronger solutions of salt and without appreciably influencing the corpuscles, as shown by the microscope.

Furthermore, an addition of sodium chloride in less amount than that in the blood (*e.g.*, 5 per 1,000) to solutions of potassium dichromate, or of other salts, which when weak dissolve the red disks, or in stronger solution occasion their swelling, will prevent the same to a greater degree than the addition of an equal quantity of the chief salt in solution. The action of the chloride of sodium is, therefore, specifically conservative.

Since the first publications on the hæmatocrit method the necessity of the presence of soluble salts of calcium for the occurrence of coagulation of the blood, and also for the formation of fibrin, has become generally known, and it has been found that these processes may be indefinitely prevented by substances capable of precipitating calcium, such as oxalic acid, or, better, a soluble oxalate or fluoride. These important facts we owe to the labors of Brücke, Hammarsten, Pekelharing, Latschenberger, Arthus, and Pages.

Latschenberger, by repeated coagulations from serum, has indeed shown that after other salts no longer appear in the coagula, calcium is still present in quantity. From this and other facts, it is now considered that fibrin is a calcium compound, although containing but one-thousandth part of this substance.

Arthus and Pages have furthermore found that by the addition of a soluble salt of oxalic acid, such, for instance, as the sodium compound in the proportion of one part to one thousand of blood, which is sufficient to precipitate all calcium in the latter, coagulation may be completely prevented for an indefinite period; that it will, indeed, be stopped if already begun, and can even be caused to disappear if not too far advanced.

Based upon the facts detailed with reference to the prevention of coagulation, on the one hand, and the prevention of the escape of hæmoglobin from the erythrosytes, as well as the prevention of their swelling, on the other, we have made and tested the following solution for employment in the hæmatocrit method: It has yielded us results of exceptional uniformity, and unlike the bichromate solution, produces no precipitation of albumin. Its formula is sodii oxalate, 2.0; sodii chlorid., 10.0; aquæ dest., 1,000.0. This solution, when mixed with blood and allowed to stand at rest, permits the corpuscles to sink with unusual rapidity, leaving a clear, almost colorless, supernatant fluid, composed substantially of diluted plasma, while the corpuscles themselves preserve their normal microscopic characters.

The chief improvement in the hæmatocrit method up to the present time has been made in the mechanical means of execution. Daland's employment of the Zeiss hæmatocytometer pipette for taking the specimen of blood increased the certainty of its exact measurement, while Gaertner reduced or removed the liability to error in the further process by directly transferring the whole of the specimen, mixed with a large and unmeasured quantity of the bichromate solution, to a tube for centrifugation, having a funnel-shaped reservoir for the same at the centripetal end. This tube, however, has been found in practice by Friedheim to leak at the centrifugal end, owing to an extraordinarily ill-devised combination of rubber cap fitted to a screw thread cut, or rather attempted to be cut, directly on the glass tube.

To avoid this palpable source of error we have had constructed[1] a new tube of simple kind, the chief characteristics of which are a closed centrifugal end, a wider bore, and a single graduation, indicating the total quantity of blood introduced. The closed end prevents all possible loss of corpuscles during the centrifugation, the wide bore permits a better extraction of surrounding fluid from the same when already tolerably compact and enables a better subsequent removal of the same, while the single graduation allows of the employment of a number of like tubes in connection with a finely graduated scale fitted to receive them.

For taking and at once thoroughly mixing the specimen of blood with the solution we have employed a tube similar to the Zeiss pipette for his leucocytometer, but bearing a single graduation corresponding to that on the centrifugation tubes. For drawing blood the sheathed lancet of Laker, which often accompanies von Fleischl's hæmometer, has yielded us satisfactory service, especially after having added to it a regulating screw-nut on the knife-shaft above the sheath. By this means the amount of projection of the point, and therefore depth of puncture upon pushing the shaft forward against a light spiral spring within the sheath, may be finely adjusted. An instantaneous and painless puncture is thus provided for, after which, by slight pressure upon the integument to the proximal side of the same, a more than sufficient drop of blood may and should be easily caused to exude.

Owing to the painlessness of the operation the end of the finger may be taken as the site of the same with the natural advantage of its abundant blood-supply. By keeping the particular point of surface supporting the exuded drop of blood horizontal, the latter will retain a globular form, thereby incurring the least expos-

[1] By Rohrbeck & Lubme, Berlin, Karl Street, 24, who have undertaken to manufacture the hæmatocrit as here specified.

ure to air and integument, which also facilitates the obtainment of the exact quantity of blood within the measuring pipette. This latter measurement is naturally the critical part of the entire operation and requires a certain amount of dexterity.

To lessen its difficulty as well as duration, we have modified the Zeiss pipette so as to diminish the sensitiveness of movement of fluid contained within its capillary portion by introducing a glass air-bulb of one inch in diameter in the course of the rubber tubing connecting the pipette and the mouth-piece of the instrument, while giving this connection altogether a considerable length for greater convenience and surety of action. By these means fluid in the capillary portion of the pipette may be easily prevented from reaching the bulbous enlargement of the same before exact measurement, which is not the case with the Zeiss instrument. To readily secure the exact quantity of blood slightly more than required must be first drawn into the pipette, when by stopping its extremity and moving the end of the pipette at right angles along the surface of the other hand, while producing slight air-pressure behind the column of blood, the latter will gradually flow out until the upper end of the column stands precisely at the mark. The specimen is then to be drawn further within the capillary, and immediately followed by about half of the clot-preventing solution into the bulb of the instrument, mixed with the same by means of the contained bit of glass, and transferred to the centrifugation-tube by the help of a bristle, the other two quarter portions of solution requisite to successively free the pipette from the remains of the previous mixtures being likewise transferred. By the employment of the above given oxalate solution, a special cleansing of the tube from time to time, as with concentrated sulphuric acid, such as is necessary upon use of a bichromate solution, is unnecessary when the contents of the tube be each time soon removed.

The centrifugation of the specimen may be performed with any centrifugal machine, and is to be continued either until the column of corpuscles ceases to perceptibly diminish in length, or, in case of comparative observations for a certain fixed period of time, sufficient to render the corpuscles compact. Wherever—as, for instance, in a case of anæmia—a simple comparison with normal blood is wished, a specimen of each may be simultaneously centrifugated and measured before the mass of corpuscles is completely compact, without impairment of exactitude. Such a centrifugation is conveniently effected with Gaertner's or Rohrbeck & Luhme's simple hand machines. In case of the former but two spinnings of the same are requisite, with the latter a revolution of from one to three minutes suffices. For retaining a level surface on the column of blood-corpuscles for precise measurement, the motion should be slowly brought to a stop.

With normal human blood, the above detailed hæmatocrit method, when the corpuscles are reduced by centrifugation to the utmost compactness, has yielded us percentages of corpuscle substance varying from thirty-six to forty-four per cent. As before stated this does not represent the volume of the corpuscles as existing in circulating blood, where, owing to the variable absorption of water from the plasma, their size is inconstant, but the amount of corpuscular substance under fixed and constant conditions effected by the oxalated solution of salt. This amount we hold to be a better measure of the quality of the blood with reference to the ingredient which forms some nine-tenths of its red disks, namely, its hæmoglobin, than those heretofore yielded by the hæmatocrit method.

Observations by F. H. Southgate upon the blood of the rabbit obtained from the subcutaneous veins have shown a generally greater uniformity than that above specified, which would indicate that blood from the capillaries is subject to greater variability than that in larger vessels.

AXIS-ADJUSTMENT: A NEW AND RATIONAL METHOD OF DELIVERING THE PLACENTA.[1]

By WILLIAM R. NICHOLS, M.D.,

BADEN, ONTARIO.

THE paper I have ventured to bring before your notice to-day, under the heading of "A New and Rational Method of Delivering the Placenta," needs an apology for its title, since it is new only in the sense that no reference to its principles can be found in any literature at hand; but it is not presumed that many of you, who are experts and veterans in the obstetric art, have failed to practise, long before the writer, some of the procedures appertaining to the method; on the contrary, it is believed that as your experience has become riper and your management more dexterous, you, too, have departed from the teaching of the schools and books, and have arrived at a practice in accord with principles I now attempt to establish. If these principles be intrinsically true and universally applicable, then the methods in vogue must be incidentally successful, and, as such, irrational, irrespective of the measure of success they apparently give; and the discussion of these principles, which this paper is sure to evoke, cannot fail to be of interest and profit; for they vitally concern that stage of labor which is admitted by all to be the most important and the most fraught with dangers and accidents to the lying-in woman.

The manner of delivering the placenta has been described as being accomplished by one of four methods, viz.: The Natural method, wherein Nature herself is competent, as she is generally with the child. The method of Traction on the Cord, now fairly obsolete. The method of Expression, as enunciated and taught by Credé, but which had been practised long before his time by the Dublin school, and taught even in our own backwoods Province by the late Dr. Workman, when professor of obstetrics in King's College, Toronto. And, lastly, the method of Manual Extraction, the last resort in failure of the former methods.

As the method of Credé has superseded the former methods, and is accepted without question as the method *par excellence*, it is to it we wish to pay our respects, and to do it the deference of quoting its technique in full and of commenting thereon. "Firm pressure is to be made upon the uterus downward and backward in the axis of the pelvic brim, when a contraction is felt to begin." At the outset, it is admitted that much success has attended this manipulation, but the same may be said of any particular procedure, in any condition, wherein nature co-operates; in other words, where success is incidental to the method, and not intrinsic or essential. The limits to which this "firm pressure" and these forcible efforts may be pushed appear to be, on the one hand, the amount of violence the woman can tolerate, and, on the other, the manual strength of her intellectual attendant. I speak of what I have seen, and, it may be, of what I have practised. I can never forget the amount of violence offered to a uterus and abdomen (not to speak of tender endothelium) at my first case of labor in a lying-in hospital. The vivid remembrance of that occasion must bear the onus of inflicting this paper upon you. Cases that cannot be thus delivered are denominated "retained placentæ;" and such retention is taught to be due to either hour-glass contraction or organic growth to the uterine walls. As I have been unable to satisfy myself of having met more than two, if even so many, cases of true organic growth of the placenta to the uterus, and not even one instance of hour-glass contraction in over half a thousand accouchements, I am obliged to consider the retention to be due in the great majority of cases to

[1] A paper read before the Waterloo Medical Association, at Berlin, Ontario.

other factors. That cases of retention are fairly frequent, we are led to believe from the histories of patients, whose statement that the after-birth was "grown fast" is by no means uncommon.

Meeting occasionally with cases of natural delivery, wherein nature is competent without any assistance from art, and, at other times, with cases of "retained placentæ" under conditions apparently as favorable, I felt myself mystified when attempting to furnish an explanation for the difference, and when I was obliged to submit my patient to the risks of manual extraction for a placenta showing no trace of organic growth to the uterine walls, or any other condition accounting for such retention, I was far from feeling comfortable and satisfied.

If a careful palpation of uteri at this stage of labor be made, it will be found that they possess marked variations in form. Some are markedly irregular and bossed, while others are fairly uniform. These variations, so far as I am aware, have met with no interpretation; they are significant, however. Reflecting that the structures superimposing the placenta—viz., the abdominal and uterine walls—are uniform in thickness, I was forced to the conclusion that the variations are due to the position of the contained placenta, but in just what shape the placenta was I could for a long time form no proper idea. An observation that I had previously made, long before I could attach to it either diagnostic import or indication for treatment, has a bearing upon this point. It was to the effect that when blindly manipulating the uterus *à la Credé*, I was on a number of occasions almost startled by a sudden slipping or jerking within my hand, accompanied by a transformation of its contents, which was manifest to the patient as well, though not painfully, and delivery generally occurred soon after without further solicitation. By degrees it began to dawn upon me that this slipping and transformation was a turning or version of the placenta upon its axis, similar in manner to the version of the fœtus at times. Further attention to these points showed that a certain rough relationship existed between the form (as felt through the abdominal walls) and the ease with which delivery was accomplished. When the uterus was fairly uniform and free from bossing, and elongated rather, nature was frequently competent, or but little difficulty was experienced by artificial methods; when the uterus was markedly bossed and irregular, and broadened rather, more placental dystochia was present, or retained placentæ were obtained.

As before stated, I regarded these variations in shape to be due to the position of the contained placenta—in other words, to the relation of the placental axis to that of the uterus.

In order to have an intelligent conception of the placenta, it is necessary to examine one that has been delivered. It will be found to be possessed of an elliptical rather than a circular form, but it is not by virtue of this that we can speak of its having an axis, though doubtless this may occasionally be so. There will be revealed, also, deep sulci or furrows on its uterine surface, which surface, before the birth of the child, presents a convexity corresponding to the concavity of a segment of the uterus, against which it is in apposition. The sudden diminution consequent upon the expulsion of the child but completes a process of folding the placenta upon itself, already initiated by its previous convexity and sulci. It is with this folded placenta we have to do—folded it may be seen when emerging from the ostium vaginæ—folded it may be felt when passing through the os uteri, and folded it lies within the cavity of the uterus. It matters not whether it is folded equally or unequally—the practical consideration being that a more definite axis has been thereby given it, which passes, roughly speaking, through the points of reduplication of its edges, these points corresponding to the poles of the fœtus. Simply its relative length has been increased. We will now define the axis of the uterus to be in that diameter which passes from the centre of the os to the centre of the fundus.

If, now, within the cavity of the uterus, the placental axis, as previously defined, corresponds to the axis of the uterus as above given, we will have, as determined by abdominal palpation, a fairly uniform, somewhat globular and elongated form. This form, I have already remarked, obtains wherein nature is frequently competent, and wherein the least dystochia occurs—the reason is obvious. If, on the contrary, the axes do not correspond, we have more or less irregularity and bossing, as the placental axis deviates from or approaches that of the uterus; the greatest deviation resulting in a "placental cross-birth," a condition much more frequently met with than fœtal cross-birth, owing to the antecedent disparity in size of container and contents, to the original site of implantation of the placenta, and the subsequent contractions of the uterus. In the condition referred to as placental cross-birth, the poles of the placenta do not present at the os and fundus, but at two opposite points midway between these. A relatively broad surface is thus in apposition with the os—too broad and too large for it to enter that opening, and any contractions occurring (which operate below the lower pole as well as above it) tend to imprison, rather than to expel, the placenta, until such times as a correspondence of axes has by whatever means occurred. In this we have the explanation for the cases of so-called retained placentæ, so common without trace of organic connection. This correspondence of axes is occasionally brought about by successive contractions indefinitely prolonged, but it is evidently the duty of the physician not to wait for the efforts of a partially exhausted organ, lest further efforts induce complete exhaustion and precipitate inertia and hemorrhage. When the axes correspond, or have been adjusted, a pole presents at the os, which uterine contractions now cause it to enter and readily dilate, by bringing into play the mechanical principles of the wedge. The blow or power being represented by the contractions, the wedge by the sloping pole of the placenta, and the resistance by the moderately contracted os.

My limited experience in this undeveloped field leads me to believe that it is possible, in the vast majority of cases, to diagnose the condition of placental cross-birth, and in cases of less axial obliquity to determine whether the upper pole is anterior or posterior, or right or left with the lower pole in a corresponding opposite position. Nor is the acquiring of this degree of refinement in palpation to be considered a feat of any comment, when slightly enlarged appendices and tubes are daily diagnosed and accurately mapped out, in abdomens having nothing of the flaccidity that is present in the third stage of labor. Who of you will affirm it to be impossible to locate within the abdominal cavity a body having the dimensions of a folded placenta? I know, gentlemen, you have met with no difficulty in palpating the floating kidney, and I believe that when you have given this subject your serious attention, you will diagnose the position of the placenta much more rapidly than I can even speak of it. The projections or bosses correspond to, and are caused by, the poles of the placenta, which the hand, rapidly swept over the fundus uteri, deeply behind it, and over its lateral and front walls, readily detects. There is also a resistance at the poles, entirely different from that at other points, and the poles located, the position is determined. Some of you may object to this, and say if it be such a simple affair to diagnose the correlations of the placenta, why is it we do not apply the same method to determining the position of the child, instead of resorting to vaginal examination? Whoever of you has had a fœtal cross-birth and has taken the trouble and care to examine the abdomen, will have been struck by the unusual form—so unusual, that in-

spection surmised the condition before palpation confirmed it. We are the slaves of habit, and are so accustomed to rely upon the vaginal examination, that we have thrown over and lost sight of the really valuable evidence derivable from external methods of examination. The fact is, that in one of the largest German obstetric clinics no other method of examination than the external is permitted in labor.

The slipping and transformation that I have spoken of as occurring when blindly manipulating the uterus, and which I have interpreted as a version of the placenta on its axis, gave me hopes that it would be possible to perform version when desired, and so obviate recourse to the dangers of manual extraction in case of dystochia or retention. Now that we have an intelligent conception of the placenta (contained or retained), and can, in the vast majority of cases, approximately determine its axis, its version or adjustment of axis presents but little difficulty.

Before attempting this, it is desirable to refer to the terms we shall use, viz.: Placental cross-birth, placental obliquity, placental version; the latter being accomplished by three methods, viz.: external, internal, and combined or bipolar.

As external placental version is the method upon which reliance is placed, we will speak of it fully, and state that it is much more readily performed than fœtal version, though much in a similar manner. We presume the hand has followed down the uterus after the expulsion of the child, has maintained its contraction, and, most of all, has determined the position of the placenta. Now, when the uterus announces, by instituting a pain or contraction, that its physiological rest is over, which has given time for blood coagulation to seal the mouths of the uterine sinuses, a period of from ten to twenty minutes after delivery of the child, we wait for the interval, that is for the period when complete contraction is absent. In antero-posterior obliquity, we proceed by grasping the upper hemisphere of the uterus in either hand more convenient, pressing the fingers well down upon the posterior wall, while the thumb searches downward over the anterior surface. When the upper pole is anterior, the thumb pulls upward and backward on this projection, while the fingers press downward and forward on the lower pole, but without any pressure whatsoever, in the direction indicated by Credé. Should a contraction occur, it will be found expedient to desist and wait for another interval. Suddenly the slipping, the transformation is felt, and version has been accomplished. The pole, the point of reflection, the analogue of the wedge, enters the os, which the finger may now make out with some difficulty, covered as it may be with membranes containing clot or fluid. When the upper pole is posterior, the manipulations are reversed. In obliquity, where the upper pole is lateral, right or left, the version appears to be more readily brought about by the two hands applied, one on each side over a pole, making proper pressure, which may also be accomplished by one hand. Placental cross-birth is managed in an exactly similar manner. The combined, or bipolar, method of version appears to be indicated only on the rarest occasions when the external has failed; while corrective pressure is made over the fundus uteri (as already referred to in the external method) by one hand externally, the other makes moderate traction upon the cord. This appears to be a perfectly justifiable and harmless procedure, notwithstanding authoritative opinions to the contrary; and an interval also is the proper time for its exhibition. When turning is felt to have occurred, we must immediately desist. A battledore implantation of the cord on the lower pole, when posterior or lateral, suggests its propriety and success; but, if on the upper pole, when anterior especially, it would have the tendency to diverge the axis and increase the dystochia, a condition actually brought about in practice at times. Internal version is simply manual extraction, so seldom to be used as only to require mentioning, in a classification of methods, as a last serious resort when former methods have failed, organic growth exists, or hemorrhage necessitates.

Now that the axis or poles have been adjusted, uterine contractions, reinforced at times by slight assistance, are sufficient to produce expulsion, if all the other factors are favorable; but it is essential that we ascertain this. In the non-gravid state the uterine axis does not normally correspond with the axis of the vagina, but subtends it at an angle. In the gravid state this anteversion, if I may term it, is frequently exaggerated by the weight of the child acting on a lax abdominal parietes, and also by the downward pressure of the diaphragm during the last powerful pains when the child is emerging. The relatively large size of the fœtal head, or breech, has the effect of obliterating this angle, and rendering for the time being the parturient canal straight. But the placenta, unable from its size to effect this, has its point of apposition on the sacrum—a solid body which opposes its progress—instead of into the lumen of the vagina, its destination. It is evidently to our advantage to adjust these axes as well, by lifting the fundus uteri and deeply depressing it into the abdomen. We will now expect, and are generally not disappointed in finding, the next or succeeding pain effect delivery, aided, only occasionally, by the slightest amount of pressure upon the upper hemisphere of the uterus, which is to be applied, not in an interval, as was the version, but during a pain. The pressure, even at this favorable stage, is not to be made according to Credé's dictum, "downward and backward in the axis of the pelvic brim," as that would move placenta and uterus *en masse*, without liberating the former. The pressure should be of a compressive nature, as it is by virtue of the resultant of this compound force that the placenta is propelled, while the womb remains behind in the grasp of the hand.

The sudden diminution in size of the womb, as elicited by the hand, announces that the placenta is expelled, which may be found in the vagina, protruding therefrom, or lying in the bed, with membranes born or unborn. Instead of proceeding to deliver these at once, we wait for uterine relaxation. As the factor of the relation of the placenta to other bodies is over, and a soft, almost fluid body as the membranes, being practically without an axis, we might consider we had nothing more to do than to twist them into a rope. Of much greater consequence is it to maintain the fundus uteri well down into the abdomen so as to render the canal as straight as possible, for the os has closed down to the size of a silver half-dollar, and intra-uterum, the membranes are spread out over its lower surface, after the manner of a fan. Considerable adhesion exists between these moist surfaces, which requires some little force to separate, and this force is applied at a disadvantage, when acting at angle. Simply hooking the fingers under the membranes is sufficient in the majority of cases, if uterine adjustment be maintained; but twisting them into a rope is a valuable device for preventing tearing.

We are now in a position to understand the incidental success of the Credé method, since (*a*) such blind manipulations, from themselves, occasionally produce version; (*b*) uterine contractions, from internal stimulation, produce version; (*c*) uterine contractions, from external stimulation, directly or indirectly, through the hypogastric sympathetic plexus, produce version. Retentions are common, which cannot be accounted for on the grounds of hour-glass contraction or organic connection.

This is, I believe, the rational method of delivering the placenta, and I hold that forcible expression, as it is now largely practised, should have no place in the methods of the modern physician; since the obstacles, which these forcible efforts are put forth to surmount

are more surely, more readily, and more painlessly removed by axis-adjustment.

TUMOR AND LARGE CYST OF THE CEREBELLUM, WITH SYMPTOMS EXTENDING OVER SEVERAL YEARS.

By J. T. ESKRIDGE, M.D.,

DENVER, COL.

PROFESSOR OF NERVOUS AND MENTAL DISEASES IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF COLORADO; NEUROLOGIST TO THE ARAPAHOE COUNTY AND ST. LUKE'S HOSPITALS.

Lucy E——, eleven years of age, white, of German parentage, was referred to me by Dr. McNaught, February 19, 1895, on account of convulsive seizures extending over a period of several years, attended by almost complete blindness. Family history was negative. The child at birth was apparently healthy, but when fourteen months old, while teething, began rolling the head from side to side, and when taken in the mother's arms the head would be retracted and turned from side to side. The child would frequently cry as if in pain. Several days after these symptoms first manifested themselves, she was seized with a convulsion which lasted about five minutes, during which there was cyanosis of the face, frothing from the mouth, the eyes were fixed and the pupils dilated. One leg was flexed at the knee and thigh, but which the mother does not now remember, both hands were clinched, and she thinks the arms were extended and rigid. About this time, or February, 1885, a thick, offensive discharge took place from both ears. The otorrhœa continued for two or three months, and during most of this time the child was restless and threw its head from side to side. From June, 1885, to January, 1888, the child was not really ill, but it remained nervous and fretful. At the latter date it had a slight attack of mumps and afterward remained in its usual condition until May, 1889, when it suffered from measles, but recovery from this seemed to be complete. In April, 1891, it fell from a wagon, striking the forehead, just above the right eye, against a horse's hoof. There was a contused wound over the eye which continued to suppurate for about two weeks. At this time complaint was made of pain in the back of the head. After this it remained in apparently good health until June, 1892, when it became very nervous, and vomited repeatedly. The vomiting was always attended with pain in the occipital region. These symptoms continued for two weeks, when it had its second convulsion, lasting about thirty minutes. This seizure began by the child crying loudly, "Mamma, mamma!" the head was retracted, and rolled from side to side, the spine was arched backward, and the arms and legs were extended and rigid. The child remained perfectly conscious throughout the seizure, moaned and called its mother, and gave evidence of great suffering. Six hours later it had a second and similar attack. The convulsions occurred two or three times every day, and on one day there were fourteen, each seizure lasting from thirty minutes to several hours. Her condition seemed to be uninfluenced by treatment, and, in fact, the mother stated that the bromides seemed to increase the seizures.

In December, 1892, an abscess formed in the right groin, which was opened a few days later, giving vent to a free discharge of pus. About this time the child became almost totally blind, remaining so for three months, the convulsions continuing in the meantime. Early in 1893 she partially regained her vision, but the convulsive seizures, which were nearly all of the same character, continued until August, 1893. From this date until December, 1894, she was free from convulsions, but she remained nervous and vision was very poor. At the latter date the convulsions recurred again and were attended with increased pain in the back of the head and frequent vomiting. She remained in this condition until I saw her, February 19, 1895, when I placed her in St. Luke's Hospital, under a trained nurse, to have the convulsive seizures watched.

Examination February 22, 1895.—She walks fairly well backward or forward and with eyes open or closed. There is no evidence of distinct ataxia in the legs, arms, or trunk muscles. The knee-jerks are slight, and ankle-clonus is absent. Plantar reflexes and tendo-Achillis are present. Lower abdominal, scarcely perceptible; epigastric, about normal. Deep reflexes of the arms are not increased. Dyn. R. 22; L. 20. While the child is not strong for its age, there is no distinct paresis or paralysis of any group of muscles. The tongue is protruded in the median line. All the general sensory phenomena and the special senses, smell and taste, are normal. Hearing watch, R. ½; L. ½. The tuning-fork is heard better in the left ear. There is no weakness of the external ocular muscles. She is able to perceive objects with the right eye, but vision is not sufficient to enable her to distinguish one face from another. In the left eye there is only slight light perception. There is an extreme degree of atrophy in both optic nerves. The retinæ are unusually vascular, and present a red, velvety appearance.

She remained in the hospital seven days, and during this time she had, on an average, from three to four seizures every day. Her temperature on admission and for a few days subsequently remained about normal, or from a half to one degree subnormal. The pulse varied from 70 to 100, the respirations from 18 to 26. During the last days of her stay in the hospital the temperature was about one degree above normal, pulse varied from 80 to 102, the respirations most of the time from 20 to 34. Her appetite was good, she was well nourished, and when not suffering from pain was bright and cheerful. Her bowels were obstinately constipated, requiring large enemas to effect a movement, as the ordinary purgatives were inefficient.

The numerous seizures that were observed did not vary greatly in character, and a description of one, with a few additional remarks, will suffice for all. I witnessed two of these attacks. While I was talking with her, she seemed to be free from pain and was laughing, when suddenly she cried, "Oh, mamma, mamma!" her face flushed, head was extremely retracted, spine arched backward, arms extended and rigid, right leg flexed at the knee and hip, the left straight, and all the muscles of the body seemed to be rigid. The hands were closed tightly. While in this condition, and apparently suffering intense agony, she was entirely conscious and would answer if spoken to; respiration, pulse, and temperature were about normal. Pupils were dilated and did not respond to light.

The spastic seizure which I observed lasted only two or three minutes, when the muscles began to relax. She seemed greatly exhausted and moaned for several minutes after the attack was over. She said that she was entirely conscious throughout the spasm and that the pain was very great, especially in the back of the neck and head. Several of the attacks observed by the nurse were twenty or thirty minutes in duration, and during some of them she would become almost frantic with the pain. On one occasion, while trying to bite her own hand, she begged the nurse to strike her head, punch out her eyes, as the pain in the front of the head was so intense. The prolonged spells exhausted her greatly, and the pain in the back of the head and neck following them would frequently continue for several hours or until she would have another attack. If the pain did not continue long after a seizure, each seizure would be followed by a period of moaning and restlessness, which would often end in sleep.

About 8 A.M., Feburary 26, 1895, the day that I had promised her that her mother might take her home, I saw her while she was eating her breakfast, consisting

of eggs, toast, and milk, which she seemed to relish very much. She was entirely free from pain, said she felt well, and was happy at the thought of going home that day. The nurse reported, however, that she had suffered from three attacks the previous night; that while all had been longer in duration and greater in severity than those which she had previously witnessed, each seizure seemed to be worse than the one which preceded it. She remained in about the condition in which I saw her until noon, when suddenly she began to scream at the top of her voice, "Mamma, mamma, mamma!" and immediately an intense rigidity seized every muscle, and the head was retracted to an extreme degree, the spine was arched backward so that she lay on her abdomen with head and feet in the air. The chest muscles and diaphragm were contracted, respiration ceased for a time, and the face became deeply cyanosed. Later, respiration became irregular, slow, and Cheyne-Stokes in character, and the pulse slow and full. This seizure lasted one and a half minutes, but she was no sooner out of one than she was seized by another of greater duration and intensity than the first. These attacks continued in rapid succession, each one growing more severe until the fifth occurred about 2 P.M., when respiration ceased. The heart continued to beat for several minutes while artificial respiration was kept up. When she died the face was deeply cyanotic.

The autopsy was made three and a half hours after death by Drs. McNaught and Hopkins. The vessels and membranes of the brain presented a normal appearance. The cortex and white substances of the brain showed nothing pathologic. The lateral ventricles were distended by about four ounces of a straw-colored, watery fluid. The left hemisphere of the cerebellum was apparently about twice as large as the right. The increase in size was apparently due to fluid in the posterior portion of the left hemisphere, while the anterior portion seemed to be nearly normal, and no undue pressure appeared to be exerted on the pons or medulla. On cutting into the left hemisphere of the cerebellum a tumor was found about three-fourths of an inch in diameter in its extreme posterior tip. The growth was hard in one portion, while in another two or three small-sized cysts containing a gelatinous fluid were found. Connected with this growth was a large cyst two or three inches in diameter and extending from near the posterior portion of the cerebellum to within one-half or three-fourths of an inch of its anterior portion, containing a thin, straw-colored, watery fluid, with here and there, and especially lying against the walls of the cyst, some rather thick gelatinous-like substance. The cyst-wall was quite thick, well defined, tough and apparently fibrous in character.

Microscopic Appearance.[1]—"The tumor consisted of two portions—one, the external, hard and almost fibrous, and the other softer. The internal portion was toward the cyst. At the sides passing into the cerebellar tissue the growth was infiltrating in character. The soft portion varied somewhat from the mere gliomatous and the more distinctly sarcomatous structure. In parts there was a marked proliferation both of the endothelium and the adventitia of the smaller blood-vessels, a new formation of capillaries, to such an extent as to give the appearance of an angioma. Many of the blood-vessels were widely dilated, and there had been hemorrhages in parts, with breaking down of tissue and the formation of small cysts. The wall of the large cyst was distinctly fibrous in character."

Simple non-parasitic cysts of the brain are most commonly the result of acute destructive lesions, usually of vascular origin, such as hemorrhage or arterial occlusion; the effused blood or disintegrated nerve elements having been removed, the cavity becomes a receptacle into which the watery portion of the blood finds access. Such cysts are often irregular in their outlines, and the wall may not be well defined. Distinct cysts of a regular shape and with firm fibrous walls sometimes form in connection with traumatic injuries of the membranes—a beautiful example of which I have recently observed in consultation with Dr. McNaught. It occurred from a blow received on the head nearly thirty years before, and gave rise to headache, mental disturbance, and epileptic seizures, which were relieved on removal of the cyst. Tumor, especially the glioma or sarcoma, of the brain may contain several small cysts, or a large cyst, as in the case just reported, may be connected with a small tumor. Such cysts have their origin most probably in the results of changes which take place in the growth, and after they attain a certain size they become much larger than the tumor from the distention of the cyst-wall by means of the watery portion of the blood. In the present instance careful microscopical search was made for granular and broken-down pus corpuscles, as trauma, distant suppuration, and otorrhœa, all causes of abscess of the brain, had been experienced by the little sufferer.

The diagnosis was a most difficult and, as proved by the autopsy, an unattainable problem—for me, at least. The history of the seizures, preserved consciousness, talking, throwing the arms wildly around without distinct clonic convulsive movements, and opisthotonus, at first suggested hysteria, but this was easily excluded by the optic-nerve atrophy and vascular changes in the fundi. If these had not been sufficient to enable me to diagnosticate an organic lesion, the attacks that I witnessed would have been ample evidence of organic change. They were typical of irritation in the posterior cerebral fossa, especially around the pons and medulla. The posterior neck muscles were as rigid as cords, the head was retracted, the spine arched backward, the masseters were at times firmly contracted, so that when she attempted to speak, her teeth, which she could not separate, were simply uncovered by the lips. The arms, rigidly extended, were thrown wildly around with shock-like convulsive movements.

Three morbid processes were considered in the diagnosis, viz.: abscess, tumor, and the results of an old basilar meningitis. The history of the bilateral otorrhœa, with a very offensive discharge, occurring about the time of her first nervous symptoms, and attended by a convulsion; the suppuration in the right groin, the origin of which could not be determined, as there had never been any further evidence of caries of the spine; and a blow to the head received just previously to the convulsive seizure becoming frequent, from an etiological stand-point were about as strong evidence in favor of cerebral suppuration as one expects to find. The subnormal temperature during the first few days of my observation of the case was also in favor of chronic cerebral abscess. The otorrhœa had ceased for a period of nearly ten years, and during this time the child had never complained of pain in the ears. It seemed to me that if the little patient was suffering from abscess of the brain the probabilities were against the ears having been the source of the septic poison, as a chronic abscess from ear infection rarely runs a very prolonged course. Headache is common to all of the pathological processes under discussion. The optic-nerve atrophy without any swelling of the disks was in favor of old meningitis and against the pressure of a growth or an abscess. I felt inclined to exclude chronic suppuration, but I admitted to the physician, Dr. McNaught, with whom I saw and studied the case, that I had not sufficient reasons to be positive in my opinion.

Between meningitis and tumor I could not decide. One of these morbid processes would have accounted for some of the symptoms, while certain ones were more common to the other. The almost total loss of

[1] By Dr. H. C. Crouch.

sight with optic-nerve atrophy, and the seizures attended with opisthotonus, rigidity of the masseters, tonic extensor spasms of the extremities, especially the superior ones, and shock-like movements of the arms are found in meningitis in the posterior fossa when the surface of the pons is irritated, and not in tumor as a rule unless meningitis is also present. So far the symptoms and the theory of meningitis harmonized, but I was at a loss to account for the other cranial nerves than the optic escaping. That the child at times should feel quite well, be entirely free from headache or any discomfort, and that there should be no rigidity of the posterior neck-muscles except during the paroxysms, seemed to me inconsistent with an old meningeal exudate in the posterior fossa. A tumor in the cerebellum so situated as to produce remittent pressure on the pons, with distinct paroxysms of increasing pressure, is common to the experience of everyone who has studied and observed cerebellar growths, but for the pressure symptoms to be apparently completely intermittent, and to return with as much regularity as epileptic seizures, and to consist solely of epileptoid phenomena without mental dulness or loss of consciousness, was new in my experience.

I confessed my inability to make even a problematic diagnosis, and advised the mother to take her child home, as I could not recommend an operation for her relief, but about an hour before the time the mother had set to leave the hospital the child was seized with a series of convulsions which proved fatal within two hours.

While the body was on the post-mortem table I was asked by Drs. McNaught and Hopkins, before they began their examination, for my diagnosis. I said that a double lesion, a tumor in one hemisphere of the cerebellum, and an old meningeal exudate would explain all the symptoms observed during life, but not the absence of others.

In the light of the autopsy which revealed the presence of a large cyst and a small tumor in the posterior three-fourths of the left cerebellar hemisphere, are the symptoms explicable? It is possible that, owing to the watery contents of the cyst, the pressure exerted by the cyst, after it became chronic, on the adjacent structures was not as great as results from a more solid and unyielding tumor, so that, while there might have been a papillitis during the early stage of the growth, the lessened pressure on the formation of the cyst and the breaking down of the growth allowed this to subside with the resulting atrophy of the optic nerves, and time had permitted all intra-ocular exudates to be absorbed. We know that a growth in the cerebellum, from its effects upon the circulation, especially in the veins of Galen and adjacent veins and sinuses, disturbs the function of the pons and medulla, usually to a slight extent continuously, and when it has reached sufficient size to exert pressure on the respiratory and neighboring centres, by paroxysms, threatening life by increased pressure which probably results in temporary œdema of the parts.

In the case of a cyst with yielding contents, which may vary in quantity from time to time, the pressure symptoms probably may become intermittent. The peculiar tetanic spasms were, most likely, due to temporary irritation of the pons and medulla.

With the information gained from the clinical and pathological observations of this case, could error be prevented in the diagnosis of a somewhat similar one? If a large cyst of the cerebellum is attended with more varying pressure-symptoms than a tumor, a problematic diagnosis might be ventured, and it might be correct or it might not. The only unilateral symptom in the case was the tendency of the right arm to become a little more rigid than the left, with, at times, a turning of the head and eyes to the right, but this was inconstant and of no localizing value in determining which hemisphere of the cerebellum was affected. Had it been possible to localize accurately the lesions, the tumor, in all probability, could have been removed, the contents of the cyst evacuated, and the life of the patient saved.

A careful study of the case just reported demonstrates how meagre and unsatisfactory are the symptoms of an extensive lesion in one lateral hemisphere of the cerebellum, and that ataxia from lesions of this portion of the brain probably only occur when they are situated so as to exert pressure on the pons, usually through the medium of the middle lobe of the cerebellum.

THE NEURO-CHEMICAL ASPECT OF DIABETES.

By C. C. THAYER, M.D.,

CLIFTON SPRINGS, N. Y.

The etiology of diabetes, after two centuries of scientific investigation, remains unsettled, and if comprehended by any, multiplied hypotheses excludes unanimity. By a physician familiar with diabetes these diversified opinions are charitably considered, for while diabetes proper exhibits some uniform and diagnostic symptoms, otherwise it appears differently in different cases and acts differently under the same treatment. The neurotic, the dietetic, the traumatic, and the toxic are varieties demanding appropriate consideration.

Its treatment, hygienic and therapeutic, is also unsettled, like its pathology. A restricted diet is best for some, a mixed diet for others, a warm climate for one, a cold climate for another. Codeia works a charm in one and a harm in another. Bromide of arsenic, reported by Clemens, antipyrin by Robin, iodine by Seagen, ergot by Tyson, and alkalies by Miathe and Dougherty, have received more or less praise, and when we have exhausted materia medica we can recommend a change of climate. Experimentation is as far as we have advanced in the treatment of diabetes, and as far as we can advance till its etiology is understood. The triangular "diabetic area" is too limited, and irritation of the calamus scriptorius too infrequent, to account for the origin and cause of this complex disease.

Saccharine urine is produced by a variety of causes, and without diabetes. Inordinate eating, drinking, worry and watching, bullet and sabre wounds in various parts of the body, have produced sugar in the urine. Diabetes cannot be scientifically diagnosed from sugar in the urine alone.

Ruling out in this paper all cases of glycosuria of dietetic, traumatic, and toxic origin, allow me to present in brief six cases which fairly represent the whole number treated, with experiments and conclusions.

Uniformity of diabetes symptoms justifies their omission and description here.

Case I.—Female, aged fifty-four, naturally strong, weight 130 pounds. After her husband's death she was worn with grief and rapidly failed, with diabetes. Six months later she came under our care, then weighing 106 pounds, passing 9 ounces of urine and 3¼ ounces sugar in twenty-four hours. She was put on codeia, ¼ grain three times per day, and gradually increased till she had taken 18 grains daily, when it was exchanged for arsenic. When she was taking 3 grains daily she passed 5 ounces of urine with 1¼ ounce of sugar. In this, as in other cases, have noticed that the maximum benefits of codeia were reached at its first physiological effects, and that beyond this it did more harm than good. When taking 16 grains for twelve hours the specific gravity was just 1000, then rose to 1024, then to 1036. Refusing food and medicine, she died three weeks after with diaceturia.

Case II.—Male, aged seventy-four; nervous, bilious temperament, and quite feeble, and was passing 7 ounces of urine and 2½ ounces of sugar daily. Put him on electric salt and stimulating baths, with massage and

oil rubs, taraxacum, gentian, and phosphoric acid, with alkalies, citrate and bicarbonate of potassium, and boracic acid, while we crowded him with a mixed diet. The urine becoming nearly normal, he prepared to go home. Having a corn on his toe, he applied some patent corn cure, which resulted in gangrene and death.

Case III.—Male, aged forty-seven ; bilious temperament, passing 7 ounces of urine with 2¼ ounces of sugar daily. Put him on a forced mixed diet, with milk, taraxacum, gentian, and phosphoric acid, with alkalies and baths as in Case II., and after six weeks discharged him cured.

Case IV.—Male, aged fifty-two. Had lost 48 pounds of flesh and was passing 10½ ounces of urine and 4 ounces of sugar daily. Put him on an absolute skimmed-milk diet, four quarts daily ; bro-arsenic and alkalies, central galvanism, salt rubs, cold sp. douche, and massage. After eight weeks was discharged cured, and has done a large pastoral work for ten years since.

Case V.—Female, aged forty-two ; bilious temperament, and had malarial fever two years before I saw her. She was passing 10 ounces of urine and 3 ounces of sugar daily. Put her on meat, milk, and salads and four quarts of water, baths, wheat phosphoric alkalies, blue-mass, ferri.-chl. et quinea. She gained thirty-two pounds and returned home cured.

Case VI.—A daughter of our vice-consul of Aintab, Turkey, aged eighteen ; naturally strong and ruddy. One month after her decline I first saw her, when her mother told me "she was passing a pail of water daily." I could not there make a quantitative test of the sugar, but it was heavy. Feeling impotent to care for the case, I sent her to our Beirut Medical College, but she was soon returned with an unfavorable diagnosis. Another opportunity for experiment. Put her on an absolute meat and salad diet, with plenty of water, but had to lock her in a room with barred windows, and her cries for bread were pitiful ; but so long as the urine seemed to improve, the parents consented to the vigorous treatment. After three weeks she was released from her incarceration, and after eight weeks she was pronounced cured ; and, having recovered from her great emaciation, she was taken to the Aintab Female Seminary by her parents and "presented" to the mission as a thank-offering, and as the first acquisition from this large Armenian family for twelve years.

We often find diabetes associated with epilepsy, chorea, lithæmia, and malarial poisoning, and attention has been called to a family type, a neurotic inheritance which characterizes a certain class of patients and accounts for many objective symptoms ; but a more numerous class exhibits disturbances of nutrition, and these may be divided into the obese and emaciated. In the obese, hepatic, glycogenic abnormalities may account for the limited amount of sugar, but in the rapidly emaciating, the entire cell structure seems besieged with a consumption or retrograde metamorphosis or chemical degeneration, the cause of which is not clear, whether chemical or neurotic, irritative or paralytic. To me the combination of all four is possible, feasible, and comprehensive as the etiological basis of this complex condition, giving rise to saccharine diabetes, and late physiologists promote this view in part.

It is the concensus of opinion among modern physiologists that the carbohydrates are cell-builders ; that by transformation they produce sugar, and the same group of sugar as we find in saccharine diabetes ; that glycogen, prominent among the carbohydrates, is widely and generously distributed throughout the body, in the cells of the liver, muscles, embryonic tissue, white corpuscles, etc. ; that glycogen leaves the liver as sugar, and that the quantity and destination of the glycogen depends on the character of the diet and a certain nerve stimulus. Glycosuria, however limited, is never insignificant, but points to a pathological condition. If there is deficiency in the selective-cell energy to reconstruct from the carbohydrates of the blood-plasma, then we have a disassimilation, a chemical metabolism resulting in sugar and tissue degeneration. If there is an abortion of the plasma, or a pathological condition rendering the plasma unsuitable for cell construction, we have sugar and tissue degeneration.

In short, the hypothesis to account for the excess of sugar in the urine is a pathological condition, a catabolism, or retrograde metamorphosis of the cell structure, or the cell plasma. And the hypothesis to account for the excess of urine is an aggravating presence of the sugar and a perversion of the secretory nerves.

In Foster's "table of the relation of the secretion of urine to arterial pressure" he says : "The division of the renal nerves produces polyuria, and division of the renal nerves and stimulation of the spinal cord below the medulla produces greater polyuria." We have seen paralysis do the same.

The most successful treatment also has been along the line of neuro-chemical indications, viz., nerve restoration and cell reconstruction. Our best treatment has been an absolute diet, either of milk, three quarts, or two quarts with six or more raw eggs daily, or meat varied in form, with salads and three to four quarts of water ; electro-thermal and salt baths ; central galvanism and faradism ; cold spinal douche from the nozzle attached to a fountain or tank, one minute morning and evening ; the needle bath ; oil and massage ; alkalies, wheat phosphates, and strychnine.

LEONARD'S METHOD FOR DETECTING CELL-MOTION.

By W. MOSER, M.D.,

PATHOLOGIST TO ST. CATHARINE'S HOSPITAL, BROOKLYN, N. Y.

The essentials to this method are : 1, Warm stage ; 2, photo-micrograph.

It has long since been demonstrated that if the white blood-corpuscle be kept at about the temperature of the living body on a warm stage—an essential accessory to the microscope—it will exhibit amœboid motion. And since the discovery of the plasmodium malariæ by Laveran, the warm stage has been frequently used to detect the varied movements of this parasite. But only recently has it come into practical use in studying the movements of the protoplasm of the red blood-corpuscle, as well as the varied phases of karyokinesis and karyolysis affecting its contained nucleus. Indeed, when we compare the "rosette-shape" exhibited in karyokinesis with the same shape exhibited as part and parcel of the life history of the plasmodium malariæ, the resemblance becomes striking, and the two might be confounded. A close observation of the cells, or other cells in the field, with the presence or absence of pigment, ought to render a discrimination quite easy. Leonard[1] studied the amœboid motion of the red blood-corpuscle in blood taken from a case of malaria. He had the cell in the field half an hour, and reproduced by means of the photo-micrograph the different movements which had taken place in the cell. In the same manner he endeavors to show that diapedesis of the red blood-corpuscle is dependent upon an inherent movement of the cell itself. The writer is convinced that this method is an ideal one, and that the observations made, and the care employed in their execution, reflect great credit upon its originator.

158 Ross Street.

Trinitrine, or nitroglycerine, has been recommended as an anti-neuralgic, especially in cases of inveterate sciatica.

Progress of Medical Science.

Cardiac Irregularity in Childhood. — Writing on this subject Professor Heubner excludes cases of arhythmia due to tubercular meningitis and to pronounced cardiac inflammation. He recognizes eight classes of cardiac irregularity: 1. The simplest case is that of irregularity after poisoning. An instance is quoted of a child who had eaten stramonium-seeds; on the third day there was decided irregularity of the pulse, which disappeared on convalescence. Large doses of digitalis and of opium have been noticed to produce the same effect. 2. Closely allied are cases of disturbed rhythm from digestive troubles. Recent investigations suggest in many severe forms of indigestion the circulation of some poison in the blood — a form of auto-intoxication. He gives an example in a child of six years suffering from gastric disorder, who began to show cerebral symptoms, vomiting, etc. There were rise of temperature, very irregular, intermitting pulse, retraction of the head, and drowsiness. It was regarded as a case of auto-intoxication, and this was confirmed by the favorable issue and the appearance of acetone in large amounts in the urine. Another case showed a slow, unequal heartbeat. 3. Cardiac irregularity may be met with in abdominal affections where no grounds exist for considering it due to poison. A case of appendicitis, in a girl of eight years, is quoted; decided intermittency of pulse was present, and also on a second occasion after an attack of indigestion. 4. Arhythmia in the course of infectious diseases is divided by Heubner into two groups—(*a*) that during the development and height of the disease; (*b*) that observed during convalescence. The first group is much the rarer. Many observers mention it in typhoid fever, but Heubner has had no experience of it. The second group is well recognized. In diphtheria it is often present, and also not infrequently in scarlet fever, of which several instances are quoted; measles and croupous pneumonia frequently give rise to it, and sometimes it has been observed by the author late in typhoid fever. 5. In anæmic and nervous children irregularity is frequently noted, and is apt to lead to a false diagnosis: in rachitic, feeble children, from two to four years old, such irregularity is too readily accepted as an indication of the imminence of tubercular meningitis. 6. Intestinal parasites are said to cause irregularity of pulse, but no evidence of it has occurred in the author's experience. 7. Under certain physiological conditions irregularity may be observed, as in emotional states, sometimes during sleep, and occasionally following a warm bath, with subsequent cooling. 8. Da Costa has described a disturbance of rhythm which appears to be the only element of disease, the child seeming otherwise well, and all the other causes being satisfactorily excluded. During febrile attacks the irregularity disappeared. Discussing the mechanism of irregularity under these various conditions, the author refers to nerve-influence—a disturbance of the regulating nerves of the heart. This is the explanation accepted for tubercular meningitis, increased intracranial pressure affecting the centres in the medulla. Irritation of peripheral nerves, such as the splanchnic depressor, disturbs rhythm, and would account for a continuance of such a symptom with nausea and vomiting. When due to poisoning the explanation is more difficult; but it is probably a result of action upon the nerve-centres or the cardiac muscle. The cause of arhythmia in anæmic, rapidly growing children is involved in doubt, though the suggestion of a relatively small arterial system is founded on experimental evidence. The treatment of cardiac irregularity in children requires a careful consideration of causes. If reflex, the irritant should be removed. When due to poison, the stomach and intestines should be emptied and a plentiful supply of water should be given to cleanse out the system. The idiopathic form requires moderate movement, light gymnastics, frequent small meals, and sea-baths.— *Zeitschrift für Klinische Medicin.*

The Diagnosis of Intestinal Rupture.—Dr. Berndt discusses the question of intestinal rupture from the diagnostic point of view, emphasizing not only the difficulty of establishing the certainty of a lesion of the gut wall, but also the importance of so doing in order to enable the surgeon to undertake an early laparotomy. The effects of a severe contusion are very similar to those produced by rupture, but the author points out that while vomiting is present in both cases, its nature varies so much as to constitute it an important element in diagnosis. In simple cases of shock the vomiting is reflex in character, and, although repeated two or three times, is never very serious. On the other hand, where the intestine is ruptured, it is due to the extravasation of the gaseous and fluid contents of the bowel into the peritoneal cavity, and is then always of a persistent and intractable character. Sundry recent investigations are added in which this opinion has been strikingly confirmed. — *Deutsche Zeitschrift für Chirurgie.*

The Influence of Alcohol on Sexual Perversions, Epilepsy, and other Psychical Anomalies.—Dr. Forel calls attention to the fact that the inordinate use of alcoholic beverages not only leads to the development of the ordinary alcoholic psychoses, especially delirium tremens, but it also plays a prominent rôle in psycho-pathology in two different ways: Firstly, the hereditary pathological predisposition of certain persons is such that they cannot indulge in alcohol moderately, but become dipsomaniacs at once, if they do not abstain all their lives. Secondly, alcoholic intoxication either stimulates or develops directly any latent psycho-pathological germs that might otherwise have remained latent. In the current casuistic of sexual perversions the principal factors enumerated are congenital and acquired dispositions, acquired nervous or mental disorders, and, in some cases, bad habits. There is no mention of alcohol as a causative factor. Forel observed cases in which the use—or abuse—of alcohol was a most prominent feature, and enumerates divers illustrative histories. It is an established fact that epileptics stand alcohol very badly, and when intoxicated are especially dangerous. There is also an alcoholic epilepsy, the subjects having fits only when intoxicated. Forel also alludes to the "pathological" intoxications, followed by amnesia, and concludes that nearly every psychosis is aggravated by the use of alcohol. Other psychoses which are either caused or kept up by alcohol are, for instance, alcoholic mania, melancholia, pseudo-paralysis, incurable secondary dementia, acute and chronic hallucinary folly, etc. Forel observed many cases cured by abstinence, and considers indulgence one of the greatest obstacles in the radical cure of morpho-mania. He had always observed that the excitement of the insane in asylums was always greater after entertainments at which wine or beer were served. At Bürgholzli, of which Forel is director, alcoholic beverages have been substitued by milk and lemonade. He commends following the example of the London asylums and that of Krapelin, in Heidelberg, by prohibiting the use of alcoholics.— *Journal of Nervous and Mental Disease.*

Antipyrin as a Hæmostatic and Analgesic. — Dr. Roswell Park advocated the use of antipyrin as a hæmostatic in surgery. It checks oozing, and is unirritating and slightly antiseptic. A four or five per cent. solution should be used. If sprayed into the nose it relieves headache, coryza, etc., and the spray also relieves acute pharyngitis.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street

New York, August 17, 1895.

SEROTHERAPY OF TYPHOID FEVER.

WE have several times referred to the attempts made by various investigators to obtain a curative serum for typhoid fever, attempts which have thus far resulted in nothing tangible.

Typhoid fever would appear, however, to offer an inviting field for the experimental use of antitoxin, for we find in it the conditions necessary for the successful application of a remedy of this sort. In the first place, the cause of the disease is known, and this cause is active in many of the lower animals as well as in man. Moreover, typhoid fever in all probability belongs to that group of infectious diseases which are self-limited, a cure being brought about by an immunization of the system effected by the action of the pathogenic bacillus, and the immunity so acquired is permanent, or at least of long duration, a second attack of the disease, after the period of relapses is past, being an exceedingly rare occurrence. Finally, and this is a matter of very great importance in successful serotherapy, a patient with typhoid fever usually comes under treatment before the disease is at its height.

The most recent experiment in the use of antitoxin in the treatment of typhoid fever, and one that seems to give more promise of success than the others in this direction, is related by Drs. F. Klemperer and Ernest Levy in the *Berliner klinische Wochenschrift* of July 15, 1895. After some unsatisfactory attempts to produce a curative milk by inoculating goats, the authors set about obtaining an antitoxic serum. For the furnisher of this serum they selected the dog, which is naturally rather rebellious to the action of the typhoid poison. The first experiments upon animals seemed to demonstrate that this serum would make the recipient immune to the action of the typhoid bacillus, and would even abort the disease, if employed a not too long time after infection.

Up to the time of the publication of their report the authors had used the serum in but five cases of typhoid fever in the human subject. Each patient received an injection of 20 c.c. for three successive evenings, or 60 c.c. in all. All the patients were in the first week of the disease. The injections were well borne and no unpleasant results in the way of skin eruptions or albuminuria were observed. The morning remission in the temperature-curve began as a rule on the third day after the first injection, and complete apyrexia was noted by the end of the second or beginning of the third week. In one case there was a slight relapse a week after the subsidence of the fever.

All the cases treated, as far as could be judged from the symptoms and temperature-curve during the first week before the injections were given, were mild ones and might have followed the same favorable course without treatment. The authors recognize this possibility and make no undue claims for their remedy. The experiments, they hold, proved only two things: first, that the serum, if it is not curative, at least does no harm, and secondly, that it does not cut the disease short, but possibly hastens its course and induces immunity somewhat earlier than the disease itself would if left untreated.

The results are not such as to inspire the hope of finding a specific for typhoid fever, but if it be found, on further trial, that the course of the disease can be hastened and its dangers averted by serotheraphy we shall at least have gained something. But five cases prove nothing, and until the serum has been employed extensively and in cases of all degrees of severity it will be impossible to predicate anything as to its real value.

THE BRITISH MEDICAL ASSOCIATION.

THE meeting of the British Medical Association, a special report of which appears in this issue, was eminently successful as regards attendance, over one thousand members being present at the opening session. This, however, was no more than was to have been expected from the fact that the meeting was held in London, which contains in itself many more than that number of medical practitioners.

The orations were by men of the first rank, whose efforts were worthy of themselves and of the audience to which they were addressed. In his presidential address Sir J. Russell Reynolds referred to a prophecy made by Dr. Parkes, the then President of the Association, at the previous meeting in London, in 1873. In speaking of Bright's recognition of the significance of albuminuria, and of Laennec's introduction of auscultation as an aid to the diagnosis of thoracic affections, Dr. Parkes made the prediction that these two discoveries marked an advance in the science of medicine which it was very improbable would be equalled in the present century.

Sir William Broadbent gave an almost new presentation of the hackneyed theme of the progress of medicine. Among other points dwelt upon was that the distinction between the art and the science of medicine was rapidly becoming narrower, and that the art which was once the all in medical practice was fast giving way to the science, although the latter might be said to be still in its infancy. He made the contention that the best physiologist makes the best pathologist, and the best pathologist the best physician, a saying that will pass as a neat epigram, and one that is perhaps also in a measure true.

Mr. Jonathan Hutchinson's address was of more than usual interest by reason of the many personal reminiscences it contained. The speaker made a strong plea for specialism, in surgery at least, and proved his consistency by the statement that he had

given up ovariotomy, litholapaxy, and some other operations as soon as he found that more practised men could do them better than he could.

Dr. Schäfer's address was mainly concerned with the functions of the internal or ductless glands of the body, functions which we are learning to regard as of the highest importance, and with the treatment of certain diseases by animal extracts.

There were a number of questions brought before the meeting which were the occasion of several very acrimonious discussions, but these are matters purely of local importance, and are of interest to outsiders only as showing that codes and general medical councils and royal colleges and medical associations are all powerless to compel obedience from the members of the profession when these members do not want to obey and are numerous enough to dare say that they do not.

A PHYSICAL SIGN OF ADHERENT PERICARDIUM.

In view of the fact that adherent pericardium often has an untoward influence upon the course of valvular diseases, any sign by which the condition can be recognized is worthy of serious attention. In *The Lancet* of July 27, 1895, Dr. Walter Broadbent calls attention to one which he has observed in four cases under treatment at the Brompton Hospital for Consumptives. One of the cases was of aortic disease of rheumatic origin, and the others of mitral insufficiency with stenosis. In three cases there was abundant evidence of adhesion of the pericardium to the chest-wall as well as to the diaphragm, but in one the heart moved freely under the ribs and the lung expanded well over it. The sign consisted in a visible retraction, synchronous with the cardiac systole, of the left side of the back in the region of the eleventh and twelfth ribs, and in three of the cases there was also systolic retraction of less degree in the same region on the right side. In all the cases there was a definite history of pericarditis, and in three of them there were other conditions strongly suggesting an adherent pericardium. "The only means of causing this retraction on both sides," Dr. Broadbent says, "would seem to be the diaphragm, which if pulled upon would have more effect on the floating eleventh and twelfth ribs than on the other more fixed ones. In cases of large heart with adherent pericardium there is a considerable area of the ventricles closely adherent to the central tendon of the diaphragm, and the powerful contraction of the hypertrophied heart must give a decided tug to the structure." That the retraction should be observed more often on the left side than on the right is only what might naturally be expected from the fact that the adhesions are chiefly to the left of the middle line; the liver also, which is often large in these cases, may, the writer thinks, restrain the movement on the right.

Honors for Irish Medical Men.—Knighthood has been conferred upon Dr. Thornley Stoker, the President of the Royal College of Surgeons in Ireland, and Dr. Christopher Nixon, the physician in ordinary to the viceregal household.

A STATE IN THE VACCINE BUSINESS.

The State of Illinois has gone into the business of manufacturing vaccine for the benefit of its citizens. It has appropriated the sum of $3,000 for the purpose of establishing a laboratory in connection with the State University, and under the supervision of the State Board of Health. The product of this vaccine laboratory is to be furnished to all physicians and health officers within the State at the cost of propagation. We presume that the example of the State of Illinois will soon be followed by other States. The immediate result of such a policy of State control will, doubtlessly, be on the whole beneficial; but we have often expressed the opinion that the relegation to State authority of so many duties that can really be well done by private individuals will have eventually a pernicious effect, since it increases the power of the government at the expense of the individual and establishes gradually a bureaucracy or a political machine.

Vaccine has been supplied in great abundance of the best quality and at a reasonable price by private individuals now for many years, and it cannot be said that the State must take care of it because good vaccine cannot be obtained otherwise. This condition of things does not perhaps prevail in Illinois.

News of the Week.

Asylum Abuses in Germany.—The private lunatic asylum of Haus Kannen, near Amelsburen, in Westphalia, belonging to the Alexian brotherhood, received a visit on July 3d from an official committee. The inquiry lasted two days, and is said to have yielded such remarkable results that the provincial administration is already considering the advisability of either buying the asylum or building a new one, to be placed under medical supervision and lay guardians. Gross defects were disclosed in the sanitary arrangements. An asylum at Mariaberg, under the care of the same order of monks, was investigated some time ago, with the result that the father superior and certain other of the monks were arrested for cruelty to the lunatics under their charge.

The Vesicating Constituent of Croton-oil.—In a communication made to the Royal Society, Mr. Wyndham R. Dunstan and Miss L. E. Boole, Lecturer on Chemistry in the London School of Medicine for Women, record the results of an experimental inquiry into the nature of the vesicating constituent of croton-oil. According to the research of Buchheim, and more recently of Kobert and Hirscheydt, the vesicating action of croton-oil is due to an acid closely allied to oleic acid, which has been given the name of crotonoleic acid, and which is now prepared for medical purposes on a large scale in Germany. The process consists, broadly, in the formation first of barium crotonoleate, and the subsequent decomposition of this with dilute sulphuric acid and extraction of the liberated crotonoleic acid as a viscid oil with ether. By a process of fractional precipitation, using lead salts, the above investigators were able to separate from this so-called crotonoleic acid a

large proportion of inactive oily acids, till at last they were successful in obtaining, by a series of operations in which alcoholic extraction and separation by means of lead oxide were made use of, a resinous substance having extraordinary power as a vesicant. The composition of this resin is expressed by the empirical formula, $C_{13}H_{18}O_4$. All attempts to crystallize or to obtain crystalline derivatives failed. It is a hard, pale-yellow, brittle resin, nearly insoluble in water, light petroleum, and benzine, but readily dissolved in alcohol, ether, and chloroform. In regard to its constitution it is concluded that the vesicating constituent of croton-oil is a lactone or an anhydride of complicated structure.—*The Lancet.*

Definition of an Habitual Drunkard.—A petition has been presented to the English House of Lords, praying that any person who has been twice convicted of drunkenness within two years shall be defined to be an habitual drunkard, and that any licensed dealer serving or harboring him after due notice shall be liable to penalties and forfeiture of license. In South Australia three convictions within six months constitute an inebriate an habitual drunkard. An Inebriates Bill, which was before the late Parliament but failed to be acted upon before the dissolution, proposed three convictions within twelve months.

Nephropexy by Tendon.—At the May meeting of the Société Nationale de Médecin de Lyon, M. Poullet presented the case of a woman upon whom he had successfully performed the operation of nephropexy by means of a tendon of the longissimus dorsi muscle, the upper end of which was detached from its muscular belly, and passed so as to make a loop, through the posterior part of the capsule of the kidney, supporting the organ and holding it in place. This ingenious method is probably the first one devised for fixation of an abdominal organ by what may be called a living suture, as one end of the tendon is not freed from its attachment. The operation was first successfully performed upon a dog, and later on the human subject.—*Boston Medical and Surgical Journal.*

The Carcinoma Antitoxin.—There has arisen quite an acrimonious dispute in Germany, between Emmerich and Scholl on one side and Bruns and Augerer on the other, regarding the efficacy of the cancer "Heilserum" described by the first named in the *Deutsche medicinische Wochenschrift.* Bruns was quoted by the authors as vouching for the efficacy of the treatment, but he now denies this and states that in no instance was a curative effect remarked, while in some cases the general state of the patient was very unfavorably influenced. Cardiac trouble and elevation of temperature were very frequent, due without doubt to a septic condition of the fluid. To this suggestion Emmerich answered that the antitoxin was originally aseptic and must have been spoiled by Bruns or his assistants. Bruns replied that the fluid was examined immediately after its arrival in the bacteriological laboratory of the university, and numerous streptococci were found in it. Augerer stated that two of his cases were attacked with erysipelas during the antitoxin treatment. The controversy has assumed a very personal character and the columns of the medical papers are filled with charges and countercharges, assertions and denials. The weight of testimony seems to be decidedly against the efficacy of the carcinoma antitoxin.

Miss Bogolubska, of Merchinsk, a mining village in East Siberia, is a lady of great determination, who deserves the thanks of her sisters in other lands. She was one of a number of Russian women who had sought in foreign countries the advantages of a medical education, denied them in their own land. After obtaining her degree from the University of Berne she returned to her native village, and, not being allowed to practise medicine, worked for eight years as a nurse. She was specially allowed by the authorities, however, to labor among the peasants who were stricken down in the cholera outbreak of 1892. This year she returned to St. Petersburgh, where she obtained permission from the Czar to take a Russian degree, which confers the right of practising in any part of the empire. This privilege is now to be extended among her countrywomen generally, and the Woman's Medical School in St. Petersburg, which was closed for political reasons in 1887, is soon to be reopened.

Small-pox in a Negro Colony.—An attempt was recently made to colonize a body of negroes from the Southern States in Mexico, but it was unsuccessful. Small-pox broke out among the colonists, and those now returning to this country are detained in quarantine at Eagle Pass. Nearly four hundred are detained there, and of these one hundred and twenty are in hospital suffering from small-pox. The number of deaths averages five a day.

International Congress of Railway and Steamship Sanitation.—A meeting of railway and steamship surgeons, and of all interested in preserving the health of travellers, will be held in Amsterdam on Friday and Saturday, September 20th and 21st. The official languages of the Congress will be English, French, and German. The membership fee is 5 florins ($2.50). Those intending to take part in the meeting should send notice without delay to the Secretary of the Committee on Organization, Dr. M. W. Pijnappel, Stadhouderskade 60, Amsterdam, Holland. Dr. H. Snellen is Chairman of the Committee on Organization.

Professor Ewald Hering, of the University of Prague, has been appointed Professor of Physiology in the University of Leipsic, in succession to the late Carl Ludwig.

Minnesota State Medical Society.—The twenty-seventh annual meeting of this Society was held at Duluth, Minn., June 19th, President Justus Ohage, of St. Paul, in the chair. The officers elected for the ensuing year were as follows: *President*, Dr. Frank Allport, of Minneapolis; *First Vice-President*, Dr. J. H. Dorsey, of Glencoe; *Second Vice-President*, Dr. E. G. Chilton, of Howard Lake; *Third Vice-President*, Dr. N. Jones, of Gaylord; *Secretary*, Dr. Ignatius Donnelly, of St. Paul; *Treasurer*, Dr. R. J. Hill, of Minneapolis.

Canadian Medical Association.—The twenty-eighth annual meeting of this Association will be held in

Convocation Hall, Queen's University, Kingston, August 28th, 29th, and 30th. The President of the Association is Dr. William Bayard, of St. John, N. B.; the Secretary, Dr. F. N. G. Starr, of Toronto.

The Medical Society of Virginia will hold its twenty-sixth annual session in Wytheville, on Tuesday and Wednesday, September 3d and 4th. The President of the Society is Dr. R. J. Preston, of Marion; the Secretary, Dr. Landon B. Edwards, of Richmond.

The American Association of Obstetricians and Gynecologists will hold its eighth annual meeting at the Auditorium Hotel, Chicago, on September 24th, 25th, and 26th. President, Dr. J. Henry Carstens, of Detroit; Secretary, Dr. William Warren Potter, of Buffalo. An interesting programme is announced.

Obituary Notes.—Dr. Baillon, the well-known botanist, died suddenly in Paris on July 18th. He was sixty-seven years old, and for twenty-eight years had held the Chair of Botany and Natural History in the medical school of the University of Paris.—Dr. Henry Gauss, aged twenty-eight, of Phœnicia, N. Y., died on August 11th, in Kingston, after a long and painful illness. Dr. Gauss was born in Utica. He graduated from Dartmouth College in 1888.

Medical Members of Parliament.—The new British Parliament contains ten members who belong to the medical profession.

State Board of Medical Examiners of New Jersey.—At the last annual meeting of this board, held at Trenton, July 22d, the following officers were elected: *President*, Edwin De Baun, M.D., of Passaic, N. J.; *Secretary*, William Perry Watson, M.D., of Jersey City, N. J.; *Treasurer*, A. H. Worthington, M.D., of Trenton, N. J.

Free Public Baths in Cities.—The author of the act passed by the Legislature of New York State, making compulsory the erection and maintenance of public baths in the large cities of the State, was Mr. Goodwin Brown, of Albany.

An International Congress of Otology will meet in Florence on September 23d, under the presidency of Professor Grazzi. Among the subjects announced for discussion are "Intracranial Abscess Resulting from Purulent Otitis," "The Pathology of the Labyrinth," "The General Treatment of Ear Disease," and "The Physiology of the Middle Ear." The Secretary of the Congress is Dr. Bobone, of San Remo.

Prize Essay on Hygiene.—The French Société de Médecine Publique et d'Hygiène Professionnelle offers three prizes for the best *mémoire* on "Preventable Diseases, and the Preventive Measures to be Taken." The first prize is 1,200 fr., the second 800 fr., and the third 500 fr. The essay is not to exceed from twenty to thirty pages of 500 words each. The following points must be treated: How to prevent contagious diseases during the illness and after; private sanitation of patients and those who tend and treat them; house sanitation and disinfection; and general sanitation during illness.

The Milk-supply of London is, according to the *Dietetic and Hygienic Gazette*, "dangerously and disgracefully adulterated by all sorts of swindling operations." The condensed milk on sale in that city is not much better, as we learn from the report of an analysis made for the *British Medical Journal* that fourteen out of seventeen brands examined were made of skimmed milk.

A School of Medical Hydrology has been opened at Luchon, in France. It possesses a good laboratory and nine professors on the teaching staff.

Successful Ligature of the Innominate Artery.—A man was recently on exhibition in London whose innominate artery was tied by Mr. Coppinger, at the Mater Misericordiæ Hospital in Dublin, in January, 1893. The operation was for the relief of aneurism of the subclavian artery. He was exhibited shortly after the operation in Dublin, and later at Newcastle-on-Tyne. The man is now fifty-nine years of age and is in excellent health. It is claimed for him that he is the only living example as yet exhibited in Europe of cure of subclavian aneurism by innominate ligature.

The Result of a Libel Suit in Australia.—Mr. C. B. Elliott, Government Medical Officer in Geraldton, West Australia, sued the Victorian Express Newspaper Company for libel. The libel was contained in the form of a letter, asserting that the large number of cripples in Geraldton was owing to the incompetence and neglect of the hospital medical officer, Mr. Elliott. After a trial which lasted eight days, the jury awarded Mr. Elliott £500 and costs, the editor being also sentenced to fourteen days' imprisonment for some contempt of court occurring during the trial.

A Bust of Carl Vogt is to be placed either in the vestibule of the University or on the Promenade des Bastions at Geneva. The original intention was to place it in the University building, but the citizens of Geneva claim that the savant belonged to the entire city, and not alone to the University, and urge that his bust be placed where it may be seen by all.

The William F. Jenks Memorial Prize of five hundred dollars, under the deed of trust of Mrs. William F. Jenks, has been awarded to Dr. A. Brothers, of New York, for the best essay on "Infant Mortality During Labor, and its Prevention." The Prize Committee also reports as highly meritorious the essay on the same subject bearing the motto, "Vade Mecum." The writers of the unsuccessful essays can have them returned to any address they may name, by sending it and the motto which distinguished the essay, to the Chairman of the Prize Committee, Horace Y. Evans, M.D., College of Physicians, Philadelphia.

Yellow Fever at Quarantine.—A passenger from Havana, who arrived on the steamship Seneca last Monday, on Wednesday developed symptoms of yellow fever and was removed to the Swinburne Island Hospital. The passenger was one of twenty-four who were detained at Hoffman Island for observation, this being the routine treatment of all persons coming from Cuban ports at this time of year, who cannot prove that they are natives of Cuba, or that they have been rendered immune to the disease by a previous attack.

Reviews and Notices.

TWENTIETH CENTURY PRACTICE. An International Encyclopædia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In Twenty Volumes. Volume III. Occupation Diseases, Drug Habits, and Poisons. New York: William Wood & Company. 1895.

THE third volume of this excellent work has appeared with gratifying promptness, which seems to indicate that the publishers' promise to bring out a volume every three months will be adhered to. The contents are of a somewhat miscellaneous character. The two longest articles are that entitled, "Alcoholism and Drug Habits," by Dr. Norman Kerr, of London, and one on "Diseases of Occupations," by Dr. James Hendrie Lloyd, of Philadelphia, both of unusual excellence. Dr. Kerr has departed here from the plan followed in his well-known treatise on "Inebriety or Narcomania," in that he treats separately of the injurious effects of alcohol and various drugs upon the habitual consumers of them, and of the morbid impulse to take these narcotics to excess for the sake of experiencing the effects which they produce. The subject of teetotalism is dealt with in a very temperate way; the argument is stated fairly and the author's conclusions are formulated quietly, without entire condemnation of those who may not agree with him in all points, or even in most points. The article by Dr. Lloyd, on the diseases incidental to occupations, is perhaps the best work on the subject that has appeared since that of Dr. Tracy in Buck's "Hygiene;" it is even more practical than the latter, which does not pretend to do more than treat of occupation diseases from the standpoint of hygiene. Dr. Lloyd classifies his subject according to causes, grouping under the same head diseases affecting men engaged in the most diverse occupations. This is, however, not a defect, but the reverse, since it saves much needless repetition, and brings more prominently into view the relation of cause and effect in the maladies under consideration. The classification by occupation has been made by the compiler of the index. The latter, by the way, is excellent. Of the shorter articles, that on poisoning, by Drs. Beaumont Small, of Ottawa, and James Stewart, of Montreal, is the most important. All the most commonly met poisons are here dealt with as regards their source, their effects in small and large doses, and the treatment of these effects. Dr. George F. Shrady, of New York, has contributed a very practical and interesting article on "Shock," and Professor Councilman, of Boston, a short but satisfactory one on "Osteomalacia." A curious subject is that of "Mountain Sickness," upon which Dr. von Liebig, of Munich, has written very entertainingly. The question is one that has merely an academic interest for those living east of the Rocky Mountains, but the practical value of the article may be tested by some of our fellow-countrymen living on the Pacific slope. The subject of "Seasickness" is handled by Dr. Albert L. Gihon, of the United States Navy, in a thoroughly practical manner, and yet in such an interesting way that it holds the reader, and almost makes him long to cross the ocean to see whether all the terrors which Dr. Gihon depicts are real or only the products of the imagination. Certainly the author, with his long experience as a sea rover, speaks as few can so fully of personal knowledge, and he has told us all there is to tell of this distressing malady. Dr. Gihon also writes in this volume on "Heat-stroke," a most seasonable topic, and on "Frost-bite," which will be seasonable in its turn.

The volume is handsomely printed, sparingly but well illustrated, and substantially bound. The completed work will certainly be an ornament to the book-shelves of its possessor, as well as a mine of information from which he can draw at will.

AFFECTIONS CHIRURGICALES DES MEMBRES. Statistique et Observations. Par le DR. POLAILLON, Chirurgien de l'Hôtel-Dieu, Professeur Agrégé à la Faculté de Médecine de Paris, etc. Paris: Octave Doin. 1895.

THIS compilation of statistics and observations of hospital surgery, especially as it concerns operations upon the extremities, dating from 1879, when the author began a service at the Pitié, has been continued at the Hôtel-Dieu up to 1893, and its publication held back till now to assure more definite results. The record, which embraces over eight hundred octavo pages, gives evidence of being carefully done, representing a vast amount of labor, and will be correspondingly valuable to surgeons and all interested in the outcome of surgical procedures and the relative frequency of the affections treated. Histories of many interesting cases are given in detail.

TEXT-BOOK OF OPERATIVE SURGERY. By THEODORE KOCHER, Professor of Surgery and Director of the Surgical Clinic in the University of Bern. Translated by HAROLD J. STILES, M.B., F.R.C.S. Edin., Senior Demonstrator of Surgery, and Formerly Demonstrator of Anatomy in the University of Edinburgh; Assistant Surgeon, Royal Edinburgh Hospital for Sick Children. With 185 Illustrations. London: Adam and Charles Black. 1895.

THIS is a translation of the second edition of Dr. Kocher's excellent treatise on operative surgery, which has already won for itself recognition as the standard work on this subject. The translation has been well done, and the illustrations are admirable.

TWENTY-SEVENTH ANNUAL REPORT, RELATING TO THE REGISTRY AND RETURN OF BIRTHS, MARRIAGES, AND DEATHS IN MICHIGAN FOR THE YEAR 1893. By the Secretary of State of the State of Michigan. Lansing: Robert Smith & Co. 1895.

THIS report contains many data of great value to the student of vital statistics. Among other features of interest are several diagrams and a colored map, showing the distribution of mortality from typhoid fever in the State during the past five years.

GESCHICHTE DER JÜDISCHEN-AERZTE. Ein Beitrag zur Geschichte der Medicin. Von Dr. RICHARD LANDAU. Berlin: S. Karger. 1895.

IN this book the author presents an account of the part taken by the Hebrews of all ages in medicine—a part by no means insignificant, especially in the middle ages, when they shared with the Arabs the honor of keeping alive the faintly glimmering torch of medical science, and when, in a period of prejudice and persecution, they were called to be the physicians of kings and popes. The work is a valuable contribution to the history of medicine as well as to that of the Jews.

ŒUVRES DE LÉON LE FORT, Professeur de Clinique Chirurgicale à la Faculté de Médecine de Paris, Vice-président de l'Académie de Médecine, Chirurgien de l'Hôtel-Dieu. Publiées par le DR. FÉLIX LEJARS, Professeur Agrégé à la Faculté de Médecine, Chirurgien des Hôpitaux. Tome 1er. Paris: Félix Alcan. 1895.

THIS is the first volume of the three which are to comprise all the works of the late Dr. Le Fort. The writings have been collected by his pupil and son-in-law, Dr. Lejars, and arranged by him in the order of subjects. We find here various articles on Hospital Hygiene, Demography, and Public Hygiene. Under each heading the articles are grouped chronologically. In an interesting article on Maternity Hospitals, written in 1866, the doctrine of the contagiousness of puerperal fever is forcibly demonstrated. In the second part we find the note of alarm on the decreasing population of France sounded, and the cause of the decrease referred in great measure to the great mortality of the new-born. Other articles of interest are on Prostitution and Obligatory Vaccination. The second volume will contain the author's writings on Medical Education and Military Surgery, and in the third will be collected all of Dr. Le Fort's contributions to the literature of General and Special Surgery. The work is a worthy monument to the author's learning and industry.

TRANSACTIONS OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS, Vol. VII., for 1894. Philadelphia: N. J. Doran. 1895.

THIS volume, uniform with its predecessors, contains some admirable papers on abdominal and uterine surgery.

THE ASEPTIC TREATMENT OF WOUNDS. By DR. C. SCHIMMELBUSCH, Assistant to the Royal Surgical Clinic University, Berlin, etc. Translated by FRANK J. THORNBURY, M.D., Lecturer on Bacteriology, University of Buffalo, N. Y. G. P. Putnam's Sons. 1895.

THIS little work is not concerned with the treatment in general of wounds, but solely with those measures which are necessary to maintain asepsis. The methods described by Dr. Schimmelbusch are those in use in v. Bergmann's clinic, in Berlin, and are naturally most thorough, and doubtless as efficacious as they are thorough. The book is one that will be found useful by the surgeon, at least the young one, and

the student who is preparing himself to be one. There is a bibliography of sixteen pages, which does not detract from the work, though it seems to be a rather useless appendix. Some of the translator's additions are judicious and add to the value of the book.

FORMULAIRE DES SPÉCIALITÉS PHARMACEUTIQUES, Composition, Indications Thérapeutiques, Mode d'Emploi et Dosage, à l'Usage des Médecins. Par le DR. M. GAUTIER. Ancien Interne des Hôpitaux, et F. RENAULT, Pharmacien de 1re Classe, Lauréat de l'École de Pharmacie. Paris: J. B. Baillière et Fils. 1895.

THIS is a little book that will be found very useful for all who have occasion to read French medical literature. Such are often puzzled by the names of special pharmaceutical preparations, which are usually called after the men who first prescribed them and contain in their names no suggestion of their composition. This compilation gives a list of all these special preparations, with their composition, indication for use, mode of administration, and dose.

THE TREATMENT OF WOUNDS, ULCERS, AND ABSCESSES. By W. WATSON CHEYNE, M.B. Ed., etc. Philadelphia: Lea Brothers & Co. 1895.

PROFESSOR CHEYNE'S book is a thoroughly practical one, and is of especial use to the practitioner who does not pretend to any degree of expertness in detail in the surgical treatment of wounds or ulcers. It deals in a very intelligent manner with the accepted methods, but is somewhat elementary for the experienced surgeon.

THE BARNJUM BAR-BELL DRILL. By R. TAIT MCKENZIE, B.A., M.D., Demonstrator of Anatomy and Instructor in Gymnastics, McGill University; Late House Surgeon, Montreal General Hospital. Springfield, Mass.: Triangle Publishing Co.

THIS book, with alliterative title, is a guide to a series of twenty-four exercises with the bar-bell. Each of these exercises is illustrated with sixteen photographs of the positions, and accompanying the text, and consists of an explanation of the movements and a statement of what muscles are called into play. A bar-bell is like a dumb-bell, with a bar several feet long between the bells.

Clinical Department.

A CASE OF MULTIPLE ABSCESSES OF THE EXTERNAL AUDITORY CANAL, FOLLOWED BY PERICHONDRITIS AURICULÆ.

BY ALBERT POHLY, M.D.,

NEW YORK.

IN looking over the literature of perichondritis auriculæ, I find that this disease is comparatively rare, and I therefore take the liberty of reporting the following case:

Miss S. W——, thirty-eight years of age, called at my office on August 30, 1894, complaining of a dull pain in the ear. She had been of previous good health, and did not know any cause for her present complaint. Upon examination I found a swelling behind the concha, nearly occluding the auditory canal. I made the diagnosis of abscess and treated it accordingly, ordering hot-water syringing and flaxseed-meal poultices. This treatment was continued for two weeks without improvement, and I therefore suggested a consultation with Dr. W. Freudenthal.

Dr. Freudenthal saw the patient with me on September 14th, and confirmed my diagnosis; made an incision, and a little pus and blood exuded. He ordered the continuation of hot fomentations.

I saw patient every day; her pain increased, owing to other small abscesses making their appearance, which were promptly opened, and the ear was syringed with a hot saturated solution of boracic acid. This was kept up for three weeks, when the swelling disappeared, but I noticed that a little polypus was forming at the same place which the abscess had previously occupied.

I again consulted with Dr. Freudenthal, who removed the polypus, partly with the snare and partly with the electro-cautery. Soon after this the helix began to swell, which was the beginning of a perichondritis. The swelling now extended rapidly, involving the whole external ear (pinna), giving the appearance of a big tumor. Dr. Freudenthal now advised an operation, which he performed in St. Mark's Hospital on November 7, 1894.

Operation.—Two incisions were made, one into the antihelix, about the middle of the external ear, the part of the greatest swelling, and a counter-incision in front of the tragus. A great amount of thick, creamy pus was discharged. The wound was then scraped, drained with iodoform gauze, and bandaged.

The patient remained in the hospital two weeks after the operation, but without much improvement, the pain being so severe that she was unable to sleep without narcotics. There was considerable discharge, with but little diminution of swelling. After two weeks patient became homesick, left the hospital, and again came to me for treatment. I saw her daily for two weeks, syringing the ear with a carbolic solution and draining with iodoform gauze; then saw her every other day, continuing the same treatment. During this period there was a marked improvement; the pain had left entirely, and the swelling diminished considerably, although there was a discharge of pus and blood, which is still present to-day; she also now complains of an intense itching in the ear. A photograph taken recently shows the existing malformation, which will in all probability remain.

Dr. Knapp, of this city, in the *Archives of Otology*, says that he has only seen three patients with perichondritis auriculæ, and he describes the following case in detail:

Patient, Henry A——, of New York, sixteen years of age, had always enjoyed good health. On August 29, 1879, he presented himself to me at the Dispensary of the Ophthalmic and Aural Institute, complaining of a moderately painful swelling in his right ear, which he had first noticed a few days previously. His ear had never before given him any trouble, and he could not ascribe the present difficulty to any cause. I found the external portion of the meatus slightly red and uniformly swollen, so as to obliterate its calibre. When the auricle was drawn back, the canal was opened to a certain degree; no ulcer or discharge was discovered, and the hearing was good. The swelling was most pronounced on the anterior lower part, where also fluctuation was discovered. The case was entered as furuncle of the external meatus, and the fluctuating part was opened, evacuating, however, not creamy but watery pus. A week later the swelling in the canal had diminished, but the lower part of the concha was red, swollen, and indistinctly fluctuating. After three days the swelling in the concha had increased, showed distinct fluctuation, and was moderately painful on pressure. It was opened, and again watery pus escaped. Four days later the swelling filled the whole concha, was dark red, and had a doughy feel. I opened it above the lobule, which was unaffected, with a Beer's knife, and let out, as before, a viscid fluid with denser yellowish flakes. A probe introduced through the opening could be pushed more than half an inch upward. The cartilage felt hard and uneven, the perichondrium was detached from it, and could, together with the skin, be easily raised by the probe. I now inserted a small silver drainage-tube, which was cleansed and re-introduced twice daily. The ear was covered with picked linen, held by a flannel roller. There was moderate discharge of thin, flaky pus from the wound. The swelling crept slowly and steadily over the whole anterior surface of the auricle, excepting the lobule. In some places it was diffuse; in

others nodular and fluctuating. These places were always lanced, and the same thin viscid pus came out as on the first opening, never any blood. In the fourth or fifth week the helix and posterior surface of the auricle were swollen, but did not fluctuate. At the beginning of the sixth week the swelling began to subside, first in the cartilaginous portion of the meatus, then in the concha, then posterior surface which had been free from suppuration, and gradually all over the auricle. The tragus assumed its natural size, the preauricular glands disappeared completely, the opening in the anterior surface of the auricle ceased discharging and closed, the auricle shrunk and remained irregularly corrugated. The antihelix, the fossæ antihelicis and scaphoidea, and the greater part of the concha had disappeared and were replaced by hardish nodules and ridges. The helix was considerably atrophied. The whole misshapen auricle was pressed against the skull, and measured scarcely two-thirds of its natural size; only the lobule escaped the deformity, because it had never participated in the inflammation.

Dr. R. Pooley, of this city, reports the following case in the Transactions of the Medical Society of the State of New York, year 1881. September 24, 1877, I was consulted by Mrs. G——, a young married woman, aged twenty-one, born in New York of German parents. She had always enjoyed good health, and up to the time when the ear disease began had nothing to complain of. Three weeks before seeking my advice she had severe pain and itching in the meatus of the right ear. She said that "a boil broke in the ear—broke, and gave exit to a greenish-looking core," after which she was better for a time; but as the ear began to trouble her again, she sought advice. No history of injury, nor had she any reason to assign for the present difficulty. I found upon the anterior lower wall of the auditory canal, just within the meatus, a conical swelling which showed the usual appearance of an otitis externa furunculosa. It was very sensitive to pressure with a probe. A deep incision was made into the centre of the swelling and a small quantity of watery-looking pus let out.

October 2d. The circumscribed swelling of the canal had subsided, but the lower part of the concha was red and swollen, although no distinct fluctuation could be made out. This swelling rapidly increased and became painful, not only when pressed upon, but spontaneously. There was now an ill-defined sensation of fluctuation present. In a few days the swelling had rapidly increased to such an extent as to fill the whole concha and obliterate its normal concavity; the swelling was of a dark-red color and boggy to the feel. An incision into the most dependent part of the tumor was made and a thin glairy-looking fluid mixed with yellowish-white shreds was evacuated. No blood escaped. The cartilage was roughened, hard, and its perichondrium, which was readily detached, raised together with the skin on the probe. A tent of charpie was inserted into the wound to keep it open, the ear covered with absorbent cotton, and a flannel roller applied, so as to exert a pretty firm pressure. There was a thin watery discharge, mixed with broken-down shreds. Slow extension of the swelling over the entire anterior surface of the auricle, successively the concha, helix, and antihelix, and the fossa helicis—in fact, all the anterior surface of the auricle, except the lobule. The character of the swelling was uneven, in some places diffuse, in others nodular. When the swelling had reached the helix it began to encroach upon the posterior part of the auricle, every part of which, except the lobule, became diffusely red, very much thickened and swollen, painful to the touch, but gave no sensation of fluctuation. Although the lobule itself did not become involved, there were two abscesses formed below it—one in front, the other behind—which were opened.

The acute inflammatory symptoms lasted for about two months, during all of which time the patient suffered a great deal of pain, always aggravated at night; so severe was the character of the pain that she had to be kept more or less under the influence of narcotics. Treatment consisted in making incisions into the parts of the swelling that fluctuated: counting the first made in the auditory canal, and the two below the lobule, eleven in all were made. In addition to keeping the lower incisions always open, injections of a weak solution of carbolic acid, and toward the last, of iodine, were made. A compress bandage, the pressure of which seemed to allay the pain, was kept constantly applied. She was given quinine and generous diet. Hearing was but little affected. The swelling gradually disappeared. The case was under treatment until March 27, 1879 (a year and a half), and considerable deformity resulted.

Dr. Kipp, of Newark, reports a case of spurious othæmatoma of both ears as the result of a burn, in a boy, aged five, showing some similarity with perichondritis auriculæ. They were treated by daily application of tincture of iodine, and at the end of two months had regained their normal size and shape. The only deformity was a wrinkled condition of the fossa helicis.

Dr. Pomeroy, in his book on Diagnosis and Treatment of Diseases of the Ear, illustrates the following case: I. S——, aged forty-two, in May, 1874, had a violent pain in the right ear, which continued for eleven days with very little abatement, when the membrane ruptured and the ear discharged large quantities of thick creamy pus, with but little relief to the pain. After one month a polypus made its appearance in the meatus and was removed. Subsequently a very painful circumscribed swelling of the meatus was incised, which gave great relief.

In July a swelling made its appearance in the region of the concha, rapidly extended to the whole of the auricle, increasing its size prodigiously. On September 1st I saw the patient for the first time, and found a large abscess occupying the region of the concha and extending upon the auricle in all directions so as to involve about half of its superficial area. It pointed both in front and behind, causing the auricle to stand out from the head at right angles. In front of the meatus, near the tragus, was a circumscribed swelling with a fistulous opening in its apex. The swelling of the auricle was somewhat nodulated, giving it the appearance of carcinoma. Fluctuation was easily detected both in front and behind, as the walls of the abscess were very thin. An incision, made posteriorly, evacuated about five drachms of pus. A finger passed into the incision revealed the fact that the cartilage of the auricle, in the region of the pus cavity, had entirely disappeared in front and behind; there was nothing left except integument and connective tissue. Subsequent to this, small abscesses made their appearance as follows: Three were incised just above the region of the lobulus, one in the tragus, and two on the upper portion of the helix. The principal pus cavity closed in three weeks without special treatment. Carbolic-acid solutions were injected at first, but they were not well borne and were discontinued. Syringing out the cavity with warm water daily was practised. The discharge from the abscess in the helix was somewhat glairy in consistency. The duration of the affection was a little more than five months. There was no insanity, present or past, in the patient or his family, and no history of previous traumatism was elicited. My opinion of the nature of this case, which coincided with that of Dr. Mathewson's, who previously had treated the patient, was that these abscesses depended on a perichondritis, and that this had been developed from an inflammation of the tympanum, which had passed outward along the meatus and involved the auricle by extension.

Regarding the etiology of perichondritis, Dr. Pome-

roy mentions injuries, burns, frost-bites, and furuncular inflammation.

Dr. Roosa says that any inflammation of the integument, connective tissue, and cartilage of the auricle, leading to effusion of serum, blood, or the formation of pus, will be apt to cause a deformity of the part, and he cites the following case:

A polypus formed from the prolonged use of poultices, the inflammation extended to the tissue of the auricle, and after a long period of suffering, during which small abscesses were formed, which were evacuated after pursuing a sinous course in the integument, the auricle obtained.

The photograph shows helix normal, anti-helix and concha replaced by a uniform intumescence; the lobule also is greatly swollen.

Dr. W. Freudenthal attributes the perichondritis in my own patient to the same cause, namely, the prolonged use of hot poultices, and I am of the same opinion.

A CASE OF PLACENTA PRÆVIA.

By MYRON E. FISHER, M.D.,

DELAVAN, N. Y.

On August 20, 1894, I was called to see Mrs. P——, aged thirty-eight, and found the following condition of affairs: She had had a severe chill two or three hours before my arrival, and I found her with a temperature of 103½° F.; pulse, 100. While sitting at the table a short time before my arrival she experienced a sensation as of the bursting of the amniotic sac, which indeed was what really did happen. The amount of amniotic fluid was rather more than we would naturally expect at full term.

The previous history of the case, as far as I was able to learn, was as follows: About two months before, while riding quite rapidly in a carriage over very rough roads, she suddenly felt a gush of fluid and immediately her clothing was drenched with it. From that time until I was called she had been flowing more or less freely all the time, but was about the house doing her work, supposing that the fœtus must have passed away. At the time of my arrival to see her I found the os dilated to about the size of a nickel five-cent piece, and there was considerable hemorrhage. This continued, and at a second examination, made two hours later, I found somewhat more dilatation and was able to feel a mass which I thought to be placenta. At the same time I could feel the cord distinctly, which was pulsating. The hemorrhage continued and I resorted to a vaginal tampon. This arrested it temporarily, but it began again. I called Dr. F. Krehbiel in consultation, and we decided that the fœtus must be removed, which was done without any difficulty, when the womb contracted down, there was no more hemorrhage, and the woman made a complete recovery without the occurrence of one unpleasant symptom.

Now there are two questions I would like to ask about this case, viz.: 1. Was the condition of placenta prævia due to an arrested abortion occurring at the time of the carriage ride two months before? 2. What was the cause of the high temperature which I found upon my arrival at the bedside of my patient?

By the way, I should have reported that this was the fifth pregnancy, all of the others having gone on to full term with normal labors.

The fœtus was about twenty-five centimetres (ten inches) in length.

The best deep anatomical guide to the subclavian artery is the lower cord of the brachial plexus, which not only lies directly over, but is attached to the sheath of the vessel.—HORWITZ.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-third Annual Meeting held in London, July 30 and 31 and August 1 and 2, 1895.

(Specially Reported for the MEDICAL RECORD.)

FIRST DAY, TUESDAY, JULY 30TH.

THERE was a very large attendance of members, larger perhaps than on any former occasion, and the Metropolitan Branch put forth all its energies to entertain its numerous visitors and make the meeting a success.

The Council met *in camera* at 9.30, but the first public function was at St. Paul's Cathedral, where the Archbishop of Canterbury preached a sermon to the members, taking as his text Rev. xxii. 1: "And he showed me a pure river of water of life, clear as crystal, proceeding out of the throne of God and the Lamb." The Archbishop said there was but one source of life, and that was life itself. There was only one law—life from life, living from living. In physical appearance, the cells in which life revealed itself were as like one another as drops of water. No analysis could distinguish them or show what their development would be. The river of life might be tainted with disease, but that was accidental, not essential to it. The accidental taint might be everywhere, even in the water which looks clearest. But in this century, he understood, new light had arisen, and the fatal germs of some diseases could be followed and slain, and it was now discussed whether immunity might not be obtained from some of the sufferings to which the flesh is heir. If this should be so it would, the Archbishop proceeded to show, furnish another analogy to Christian doctrine.

In directly exhorting members the preacher dwelt on the necessity of reverence, which was so important a characteristic of the true *religio medici*. Their study, he said, was not life, but rather the effects of life, and in the study of that mystery it would be strange to forget reverence.

The first general meeting of members opened at 2.30, and occupied most of the afternoon. Dr. Long Fox, the retiring President, could find no words in which to express his appreciation of the kind reception he met with from the large and influential meeting, but should not think of detaining them. Sir W. Hingston, M.D., then proposed a vote of thanks to the retiring President, which was seconded by Dr. Cousins and carried unanimously amid great applause, and Dr. Long Fox was elected a Vice-President of the Association for life, and returned thanks in a few words.

SIR J. RUSSELL REYNOLDS, the new President, then took the chair, and moved the adoption of the report, which was taken as read.

The President referred to the growth and satisfactory state of the Association, which numbered sixteen thousand members and was the largest and strongest association of medical men in the world. He mentioned that on the occasion of the first anniversary meeting the members of the Association were under one thousand five hundred, but a few years afterward they had increased to five thousand, and year by year it augmented in numbers and vitality.

The President then referred to the exhaustive report of the Association on the workhouses and the poor law administration, which had stimulated the authorities to effect some much-needed reforms, and especially to more consideration for the poor. The medical act needed reform, but on public grounds, not from a merely professional point of view. The habitual inebriates should be dealt with by the County Councils, who should have the power to deal with them

with a view to their reformation, which would never be brought about by sending them to prison, as was done under the present system.

Dr. Ward Cousins, President of the Council, was of the opinion that special deficiencies required special treatment, and referred to the assistance given to associates in the south of Ireland which had enabled them to gain a victory in their contention with the authorities. The Association had sustained many losses during the past year, and some eminent names had been removed by death from the list of members. The medical profession had its successes and its disappointments, but it was a noble one and worthy of the best men in the community.

The Treasurer, Mr. Butlin, would not detain them long. The assets of the Association in excess of all liabilities amounted to the sum of £60,000, and they were approaching a condition of prosperity, but the profits for the year were £4,000 or £5,000 less than for the previous twelve months.

Dr. Douglas complained that the report had been issued so late that a great many members had not had an opportunity of reading it, and he considered that they ought not to be asked to pass what they really know little or nothing about. If they were told that this was in consequence of the Council having met but recently, all he could say was that they should have met in time to issue the report earlier, so that the members might have had an opportunity of considering it before being asked to vote on it.

Dr. Campbell spoke about the registration of midwives and the suppression of illegal medical and surgical practice. He had noticed with surprise, in a recent number of the *Journal*, an advertisement from a man whose name had been removed from the Medical Register, and he wished to ask the President of the Council how it was that such a grave mistake had been made.

Dr. Ward Cousins replied that the Council had nothing to do with the advertisements.

Dr. Campbell then expressed an opinion that the editor should be held responsible, and if he would not, or could not, then some one else should be appointed in his place who would be more in harmony with the bulk of the associates.

Reference was then made to a case in which it was contended that the Association should have rendered monetary aid to a member of the Association, to which the President replied that the Council were in sympathy with the gentleman in question, but they had no power, according to the memorandum of association, to divert any money to such a purpose.

The Treasurer was then asked a question as to the lease of the Association's premises in the Strand, which he said would expire in ten years. In reply to further questions, it was stated that the increase under the head of Editorial Staff was distributed in payment for further clerical assistance to meet the increasing expansion of the *Journal*, as well as for the payment of contributors on all sorts of subjects, from all parts of the world. The exact amount of salary received by the editor was stated to be £1,150 per annum; when they (the Association) were poorer, they paid their editor less, and now that they were better off, they paid him more. Other items of expenditure were referred to designing and executing illustrations, and to increase of actual material used in the production of the *Journal*, and the demands of an enlarged and constantly growing circulation.

An elderly member then spoke at some length, but his remarks were quite inaudible, except to a few members in his immediate vicinity.

The President then put the reception and adoption of the report, and this was carried, with a few dissenting voices.

An interim report on the state of general practitioners during the past year was then considered, and the question of the proposed registration of midwives was awarded a great deal of attention, if nothing new was advanced in opposition to the scheme. Some members denied that the proposal was a retrograde one, and others objected to it on the score that it created, or would create, an inferior grade of practitioners of medicine, and advocated the better education and training, with a view to registration, of medical, surgical, and obstetrical nurses. The care of the parturient woman should not be delegated to any intermediate class of practitioner. The Midwife Registration Bill was not now before Parliament, because no Parliament was now extant, and when it was constituted, if the bill should come before it, it would have to be introduced *de novo* as an entirely new bill, and the necessary amendments might be made in it and safeguards be added as required.

Dr. Ward Cousins said that the Council had no power to institute proceedings for illegal practice, nor had they any power to control it in the interest of the public. The authority that should prosecute in such cases was the General Medical Council. The Council of the Association had taken high legal opinion, and it was adverse to their interfering in such matters. True, the memorandum of association might be altered, but that could not be done without entirely changing their constitution, which had for its object the promotion of the honor and interests of the profession. At present they had no power to prosecute quacks, nor was there any unanimity upon the question of their moving in that direction, and until there was there was no possibility of an alteration being made in the memorandum. At the same time, when he advocated caution he did not at all mean that nothing should be done, and advised the objectors to join some of the "medical defence unions" which were in existence, and get more members on the General Medical Council, which was now made up of what might be termed the privileged class.

Dr. Rentoul said that the *Journal* was in favor of the registration of midwives, and the bulk of the associates were opposed to it.

Mr. Lawson Tait then moved an amendment to the report to the effect that the members of the British Medical Association condemn the formation of a new and inferior grade of practitioners, which was received with great applause by the meeting. He complained of the *non possumus* attitude of their Council. An improvement in the status of the midwife was necessary, but was registration the right way to effect it? He said "no," emphatically, while the other side regarded it as inevitable by the pressure of public opinion. But such a step would be retrograde, downward and backward; medical ladies especially would be handicapped by it; and if a number of qualified females were registered what was to prevent unqualified male assistants from being registered, too? The registered midwife would have no responsibility and be under no control. The poor would not be benefited by the registration of midwives, but would, on the contrary, have a grievous wrong inflicted on them, by being handed over to the care of any woman who had ever been present at a birth and considered herself thereby qualified to be a midwife. If the stigma of pauperism was removed from persons obtaining obstetric assistance from the parochial medical officer much good would be done, whereas now men were politically degraded if their wives were confined in the workhouse.

Dr. Colin Campbell was far from complaining of their old friend "Sairy Gamp." He had experience of her for more than twenty years, and he must say that he had no knowledge of any such horrors as he had heard and read of in her regard; on the contrary, it was the new Sairy he found intolerable, the nurse-midwife who had been trained for three months in a lying-in hospital more or less efficiently, and who considered herself "educated" and on a par with (he might have

said better than) the medical practitioner. The Obstetrical Society of London had been giving out diplomas by the yard to such persons. He had never had any trouble with the old order of nurses—they knew their place—but he had with the new, which did not. What did their Council do toward opposing the mischievous Midwives Registration Bill? Nothing. A bill that placed women of the Sarah Gamp stamp on a level with us was derogatory to the honor of the medical profession. He then read an advertisement from an "Anglo-French" firm that practically offered to procure abortion and to provide midwives, and asked if such persons were to be registered. It was a false philanthropy to attempt to pass off a three-months midwife as a person capable of attending on the poor, and to represent her as quite sufficient for them was an abomination. More deaths took place after than during parturition. What we want are thoroughly trained nurses and not Sairy Gamps registered as midwives.

Dr. Kemp asked was it philanthropy that actuated them in their opposition to the registration of midwives. (Cries of "Yes!" "Yes!") were they to ignore the millions (*sic*) of women who gained their livelihood by acting as midwives (laughter)? They seemed very impatient to come to a wrong conclusion; therefore, as they refused his services in their pangs (laughter), he would withdraw them, and he then sat down amid roars of laughter from all parts of the hall.

Mr. Victor Horsley did not pretend to any special gynecological knowledge, but he thought the question of the registration of midwives was not before the Association, though that of the registration of midwifery and other nurses was, and the rider to the motion moved by Mr. Lawson Tait had no bearing on the question.

Dr. Reid in a very excited fashion apologized for the midwives whom he had been largely instrumental in educating; it was a question of £ s. d. (Cries of "To whom?" and uproar, amid which the doctor sat down.)

Dr. Hayward said many poor women could not afford to pay more than two or three shillings for a midwife, and wanted to know where they would find a doctor for that; such a matter was not to be decided by that meeting. (Uproar.)

Sir B. Walter Foster had not intended to intervene in the discussion, and should not have done so but for the attempt of the last speaker to throw dust in the eyes of the meeting. He (Sir W. Foster) was by no means opposed to improvement in the education and training and cleanliness of midwives, and if it was insinuated that they were opposed to that the statement was a false one. He then pointed out the danger to parturient women from incompetent midwives and advocated well-trained midwifery nurses. Registration would open the door to the formation of a low-grade order of practitioners, covering the whole ground and encroaching on the domain of medicine. The diploma only allowed the midwife to attend a natural labor, but the Registration Bill eliminated this safeguard. He heartily supported and called upon them all to vote for the rider named by Mr. Lawson Tait.

An associate considered the registration of midwives a necessity; no new order of practitioners would be established. (Cries of "Vote!" "Vote!") He spoke on behalf of the women who wanted to be attended by women and not by men, and would prefer the midwives should have some training, rather than none. He was sorry to see a great Association ranging themselves on the side of selfishness. (Groans and hisses, during which the doctor resumed his seat.)

Another associate did not stand there to utter a word against the honor of the medical profession, nor to be lectured by specialists. (Ironical cheers.) They wanted to get the spurious metal hall-marked; a nurse acted under control and a midwife independently.

Mr. Wheelhouse wished as one of the Direct Representatives in the General Medical Council to say a few words to the meeting. He was utterly opposed to the notion of hall-marking spurious metal, to the admission of ignorant women into a position that meant ruin to the medical profession. No one could tell how a labor would turn out until it was over, and an ignorant woman would not recognize danger if it arose.

Mrs. Scharlich related her Indian experience, and said that no members of the profession felt the danger of unqualified practice more than the medical women. It was a mistake to suppose that they (medical women) were prepared to accept a minimum fee, but there were exceptions, and people liked to have a qualified person when they could have one.

Dr. Murdoch Cameron moved and Dr. Hayward seconded an amendment to the effect that the Association approved of the system of registering midwives, and when this was put to the meeting only forty hands were held up for it. The amendment was therefore lost.

Mr. Lawson Tait's rider was then put and carried almost unanimously. A member then wished to put another amendment, but was ruled out of order by the President and sat down very reluctantly.

Protection of the Profession.—Dr. Arthur Welsford moved, and Mr. Bullar seconded, "That it is to the interest of the public and of the profession that the Council of the Association should take power and authority to protect both the individual and collective interests of the profession, and that the Council be requested to take such steps as may be necessary to enable it to actively undertake these duties."

Both mover and seconder urged immediate attention to this important subject, the seconder declaring it as necessary to put down quackery inside the profession as it obviously is outside. Dr. Mackenzie, representing the Devon and Somerset branch, supported the resolution, and declared that so strong a feeling existed on the subject that unless it were met defections from the Association must be expected.

The motion was agreed to and some further notices were adjourned, and the meeting closed with a vote of thanks to the Chairman.

Evening Session.

President's Address.—The evening general meeting, which was pleasantly combined with a conversazione, was held at the Imperial Institute at South Kensington. The members and guests were received in the beautiful vestibule by the President and other members of the Executive and Reception Committees. The President's address was afterward delivered in the temporary Great Hall. To pass to this barn-like wooden structure from the marble staircase of the vestibule, with its fine proportions and noble pillars and roof, was to suffer a disappointment of one's æsthetic expectations. Unfortunately the address hardly compensated most of those present for this disillusionment, as, owing partly to the bad acoustic properties of the shanty, and partly to the noise outside, Sir J. Russell Reynolds was only audible to those in his very immediate neighborhood; so much so that when the tempting strains of the Strauss orchestra were wafted in through the windows, the bulk of the audience gave it up as a bad job and left for the gardens and the conversazione.

Sir Russell Reynolds said that it was twenty-two years ago that the British Medical Association last met in London. At that time Sir William Ferguson was its president, and could that distinguished surgeon have fallen asleep after that meeting and awakened only this year, he would have had difficulty in believing the reality of what he saw. Those of us who were privileged to know him, remembered his coolness in emergencies, his operative dexterity, and his skill in meeting the most unexpected accidents. Yet to-day those who had been his dressers would be found performing, as a matter of course, operations from which even he would, in the state of our knowledge twenty

years ago, have shrunk aghast. In 1873, Alexander Parkes delivered the address in medicine, and he, too, would be surprised could he witness the progress made in medicine, and especially in preventive medicine.

Of great advantage to the profession in England was the establishment of the conjoint examination by the Royal College of Physicians and Surgeons, and the erection of the Examination Hall, where now so much valuable research work was carried on. The student of to-day is a far more earnest and hard-working individual than his predecessor of twenty-two years ago. At that time there was no lack of teaching, but even the teachers scarcely believed the half of what they taught, and did not fully understand it.

The speaker referred to the present state of nosology, and regretted the tendency to label diseases or groups of symptoms with the names of their discoverers or those who first published descriptions of them, as tending to divert attention from their true relations. He deprecated equally Mr. Hutchinson's proposal to call newly described disorders by the names of the patients who were first noticed to suffer from them.

Of late years microbiology and the germ theory of disease had attracted more and more attention, as had the functions of structures such as the thyroid, the adrenals, and the pituitary body, which were formerly unknown, but now bid fair to reveal themselves.

The protective and curative power of the products of disease germs was also a new discovery, which was of increasing importance and promised great benefits to mankind. He feared that in our social life there was a loss of reverence, "that angel of the world," and that much which now passed for wit or cleverness is only an offence against the religious opinions of others, or the long-recognized standards of propriety. He said that he would not quote the hateful phrase which was used to characterize this class of thoughts and actions, but he did not think that the "end of the nineteenth century" had much to do with it. Children may strip themselves as high as they please to paddle in the edge of the ocean, but when in the later years they roam, as society now sanctions, on the shores of the ocean of Time, the results might be disastrous to themselves. With regard to the attitude of the profession toward the religious element in men's nature, we should be careful to do and say nothing that could damage what was a very real solace and comfort to many in suffering and trouble.

After a vote of thanks had been proposed, seconded, and carried by acclamation, the audience adjourned to the garden, the appearance of which was most inviting, lit up by many colored lights and filled with brilliantly dressed ladies and sombre-coated men. The Strauss orchestra and a military band enlivened the proceedings, and the refreshment buffets were well patronized. It was nearly midnight ere the last visitors left.

Second Day, Wednesday, July 31st.

The morning of the second day was devoted to sectional work. In the afternoon the second general meeting was held, when the address in medicine was delivered, after which the business adjourned from the former general meeting was resumed.

The Address in Medicine was delivered by Sir William Broadbent. Before the address was begun Dr. Ward Cousins made the announcement that no place had been decided upon for holding the meeting next year, nor had any decision been come to with regard to the President elect, but he hoped by the next quarterly meeting to be able to announce that both points had been settled.

Sir Russell Reynolds then introduced the lecturer (Sir W. Broadbent), who began by saying that a very heavy responsibility had been placed upon him by the Council and Association; they had also given him a rare opportunity and conferred upon him a very great honor. The temptation to take up some special subject as the text of his address had been very great, but he had resisted it, and decided to consider the growth of the art and science of medicine from early times.

The art of medicine had always preceded the science and had always been considerably in advance, but science was established upon the firmer basis of skill in the recognition of disease, and until science threw light upon it the progress of the medical art had been but slow.

True science consisted in the application of science to the facts revealed by observation.

The identification of the various forms of disease was, at first, scarcely worthy of the designation of diagnosis, but was simply the attaching of a name to a series of symptoms. Remedies for various diseases were due to the observation of the instinct that impelled many animals to have recourse to various substances when suffering from disease, and experience afforded a further corroboration of the value of the remedies thus indicated.

Of the infancy of medicine we know little or nothing, but even in the time of Homer the healing art was known, and the Chinese had practised medicine from a very remote period. Hippocrates was the first of the ancients of whose theory and practice of the art of healing we have the best knowledge; bleeding was practised as well as cupping, and the valuable properties of opium were also known to him as well as the use of enemata, suppositories, and fomentations. Hippocrates flourished somewhere about 400 B.C.; he was a contemporary of Socrates; he had little true knowledge and his physiology was extremely imperfect. The attitude of his mind was directed toward the relief of disease as thus differentiated, and in this he was guided rather by observation than by theory. He could not, however, entirely escape the influence of the latter, but he generalized from observed facts. His idea of "critical days" in the progress of disease was derived from the natural history of febrile attacks, and that of "humor" from the discharges in such complaints, for instance, as coryza; the condition of the stools in diarrhœa also served to confirm the latter theory, for he noticed that a certain lapse of time intervened between the commencement and end of an attack, and he was thus enabled to predict the date of the critical day.

Another theory was that four humors existed, whose harmony constituted health, and their discordance, or the preponderance of one of them over the others, constituted or caused disease. His careful study of the cause of disease has made him a model for the physicians of all time. The dissection of the human body was practised in the time of Galen, whose views dominated medical art for a period of fifteen hundred years. He was an apt follower of Hippocrates, for he made observation the basis of his practice, though his imagination led him to theorize; but his observations were directed by excellent common sense, while his knowledge of anatomy was very superior to that of his master Hippocrates. He recognized the difference between sensory and motory nerves; his physiology no doubt was fanciful, but, nevertheless, he made some noteworthy discoveries—for instance, that urine was secreted by the kidneys and was conveyed into the bladder by the ureters; and when this idea was ridiculed by his contemporaries, he proved it by applying ligatures to the ureters; he came very near to the discovery of the circulation of the blood, and knew that the arteries contained this vital fluid, though he also believed them to convey air through the body. He wrote upward of one hundred treatises on matters connected with the science and art of medicine. That on the localization of disease was very true to nature, and his description of various symptoms was remarkably correct. For example, his account of dysuria affords evidence of his robust common-sense, and is singularly accurate: A child had suppression of urine which was

referred to the lodgment of a stone at the neck of the bladder; the patient was to be placed on his back with the pelvis elevated and the knees flexed, he was then to be shaken smartly, when the stone would slip from its position and urine would be immediately voided; if not, the patient was to be shaken again more vigorously than before, and if relief was not then obtained, he was to have a catheter passed, in order to dislodge the stone.

Galen's materia medica remained in vogue for a long period, one of the principal remedies being theriaca, which consisted of a variety of substances of which liquorice was one.

Both Hippocrates and Galen rejected the doctrine of the empirics, which referred all disease to alternated relaxation and constriction. The followers of Mohammed found the writings of these fathers of medicine in the library of Alexandria, and the ideas contained in them were largely adopted by the Arabian physicians, which brought them once more into prominence.

The small-pox, which was brought by the Saracens into Europe, was thought to be due to the presence of a particular ferment in the blood.

The great plague, *circa* 1348, and the sweating sickness of 1485, left no mark on the therapeutics of the world, but when syphilis appeared, in 1494, guiacum was held, though it is difficult to account for the fact, to be a certain specific, but it was soon superseded by mercury, fumigation being practised then with the latter drug as well as inunction.

In the fourteenth century the dissection of the human body and its post-mortem examination were both practised. In 1518 the art of medicine received a prodigious impetus, by the labors of many eminent physicians, and in 1628, Harvey made his great discovery of the circulation of the blood, which has made an epoch in biology, but his knowledge he derived from Fabricius (?).

It was a long time before the great discovery had much practical effect on the medical art; indeed, the first conclusions from it were absurd, if not positively mischievous.

The nerves were also supposed to circulate a special fluid.

Sydenham and his contemporary Boerhaave, *circa* 1680, offer an interesting comparison with Hippocrates and Galen, and the most important addition to the materia medica in their time was "bark," of which the great English physician had a high appreciation; he also advocated the employment of mercury in the treatment of many diseases, and had a high opinion of antimony. Nature, he thought, was engaged in the expulsion of various peccant substances from the system, and the wisest physician was he who rendered her the most effective aid in her laudable efforts.

It is more difficult to know when, where, and how to act than it is to determine what is to be done; any apprentice will tell you in a moment what to give to purge or make a patient vomit, but it is not so easy to determine when those effects are to be produced. Much perversity is often displayed in the application of new discoveries, but we have now reached a point in the progress of medicine when we can have no other guide than science.

Physiology as a science depends on the appreciation of physical and chemical laws; Harvey's discovery was a barren one until the recognition, or discovery, by Lavoisier, of the phenomenon of respiration, by which we arrived at the knowledge of blood tension; while the microscope gave an expansion to knowledge that cannot be over-estimated.

Lavoisier discovered the rôle played by oxygen in combustion, and his recognition of its analogy with the function of respiration was both a revelation and a revolution, and it was chemistry that demonstrated the relationship.

Chemistry interprets the relation existing between structure and structure; every vital act is a chemical act, and chemistry is the link between pathology and therapeutics.

Morgagni was the founder of pathology, and Hunter, Virchow, and others gave it new developments. Clinical observation has always been in advance of physical diagnosis, but the latter has been much advantaged by percussion, auscultation, and the clinical thermometer, which constitute epochs in its development; the last especially has revolutionized therapeutics, and it is difficult to imagine now how anything could have been done without its assistance, not only in the diagnosis but the treatment of pyrexia; and yet its introduction is of very recent date. Our knowledge, too, of the various ductless glands of the body and their functions, has been greatly improved of late, and we know that their rôle is to supply something to, not to withdraw anything from, the system.

The discovery of the part played by micro-organisms in disease and the discoveries of Lister, whose infinite capacity to take pains constitutes genius, as well as the discoveries of Pasteur, can only be mentioned, but thanks to their labors we have ascertained the important function of bacteria and their products in the causation as well as in the alleviation and cure of disease.

What bearing has all this on therapeutics? The best pathologist is the best physician.

New remedies are introduced every day, chiefly for the benefit of those who do not know how to properly use the old ones. The physiological action of a drug is inferred from its chemical constitution, and therapeutics only waits for an answer to the questions she puts to chemistry in order to become a science.

There are still new fields to be conquered, for there is much in connection with the art of medicine that is far from being fully understood; in this personal experience is the best guide and finds expression in theory; but no theory is of universal application, although homœopathy, a relic of old times, pretends that the contrary is the case; but we are in danger of being carried away by fashion.

There is no universal panacea, though there are small working hypotheses, gout, for instance, to one, and something else to another, who get hold of one idea, apply it to everything, and stick to it through thick and thin: what we really meant is to treat the patient and not the disease.

Reverting to the prevention of tuberculosis, Sir William said that antiseptics would destroy organisms when present, but care should be taken that in lowering the temperature we did not also lower the patient. Nature, he thought, was no bungler, but knew her business, and no doubt had an object in raising it.

At no time than the present had the science of medicine and its professors more right to be congratulated on its progress, and never have both stood higher in the estimation of the world.

Dr. Pavy then proposed a vote of thanks to the lecturer, and remarked that science should always be the foundation of art, but the latter anteceded science as a rule, but they were getting nearer and nearer to their proper relative positions. The address to which they had just listened could only proceed from a mind of a high order, and he would only say that it was worthy of the man who had given it.

Professor Cumming seconded, and said that in all times the leaders of medical thought were not only great physicians and surgeons, they were also great men. Far from being too conservative, we (medical men) are only too ready, he thought, to take up new ideas.

Dr. Pavy stood up to put the proposed vote to the meeting, and then said, no, he would not put it (great applause). Vote of thanks carried with acclamation.

Dr. Keating, of Toronto, then came forward to convey the cordial greeting of the medical men of On-

tario to the great British Medical Association. No body of men in Canada was more loyal than they, their medical association numbered some three thousand members, and they took a great pride in the associations, in which they were determined to live and die.

The Midwives Registration Question Again.—Mr. Victor Horsley moved the adoption of the report of the Parliamentary Bills Committee. The bill for the amendment of the medical acts that was before the last parliament was, he thought, too narrow, and should have embraced the constitution and procedure of the General Medical Council; the committee had referred the matter for consideration to a sub-committee that had only had time to consider one point, namely, the Registration of Midwives, and the sub-committee asked to be reappointed in order to give full consideration to the whole subject.

The report was received and adopted unanimously.

Dr. Lovell Drage offered an alternative to the Registration of Midwives, namely, the improved education of the male medical student in obstetrics. Puerperal fever was supposed to be carried from one patient to another by ignorant women, but the greatest parturient mortality was referable to the accidents of childbirth and not to puerperal fever. No one should be permitted to undertake the practice of midwifery who had not previously attended a large number of cases of parturition. He then proposed the following "rider" to the report, although Dr. Ward Cousins thought it unnecessary as the subject was under the consideration of their Council, whereupon Dr. Drage retorted that surely the Council should not object to have their hands strengthened.

Rider: "That we view with deep concern and regret the recommendation of the General Medical Council to the medical examining bodies that they should admit students to their final examination who present a certificate that they have 'conducted personally' only three, and 'been present at' only nine confinements; and as the General Medical Council has refused on November, 1890, to alter this recommendation, we instruct our Council to petition the General Medical Council to recommend that no student be admitted to his final medical examination until he presents a certificate showing that he has personally conducted at least thirty confinements under the direct supervision of a registered medical practitioner. We also instruct the Council to take immediate steps to have Section 20 of the Metropolitan Poor Act of 1869 repealed, which prevents workhouse infirmaries from being used for the clinical instruction of medical students in practical midwifery, while pupil midwives are now admitted; and also to petition the committees, medical staffs, and, if need be, the subscribers to the City of London Lying-in, the British Lying-in, and the Clapham Maternity, to withdraw their rule which excludes male medical students from clinical instruction at these hospitals, seeing that these are now used by pupil midwives."

This was seconded by Dr. Rentoul, who said he must again refer to the scandalous fact that men were turned out to practise midwifery after attending three labors!

After some discussion a vote was then taken on the report, which was declared carried. The rider was then put to the meeting, and speaking in support of it, Dr. Ritchie, of Manchester, said that students had to take their instruction in midwifery from the midwives, and Dr. Draper added that the latter had to be "tipped."

The rider was then carried unanimously.

Dr. Rentoul moved another rider with reference to the direct representation of general practitioners on the General Medical Council. Sir Walter Foster and Mr. Wheelhouse supported the proposition, and the former said that he had done his best, but they were five to twenty-five, and he had received no outward support from the profession, although during the last three years he was in a position, as a member of the late government, to have done something to forward their views.

On reference being again made to the instruction of students in midwifery, Dr. Ward Cousins said that the Council was of opinion that careful personal instruction in three cases was better than attendance on thirty cases, in some of which, at least, the only part taken by the student would be to rest his hand on the bed-post and look on. (Laughter and cheers.)

Dr. Rentoul's rider, seconded by Dr. H. Woods, was then put and carried unanimously.

Dr. Norman Kerr then moved the adoption of the report of the Committee on Legislation for Inebriates, and observed that inebriation should be treated as a disease and not as a crime. Inebriate houses were not prisons, and with reference to the infringement of personal liberty, was not this done every day in the case of lunatics who had never been guilty of crime? Seconded, and adopted unanimously.

The report of the Therapeutics Committee was also moved, seconded, and adopted, without dissent.

The report of the Medical Charities Committee was moved by Dr. Bridgewater, seconded by Dr. Brown, and adopted unanimously.

The report of the Committee for the Efficient Control of Railway Servants' and Mariners' Eyesight, was moved, seconded, put to the meeting, and adopted unanimously.

The report of the Committee on the Mental and Physical Condition of Children, to the Council of the British Medical Association, was moved by Dr. Bridgewater, seconded, and adopted unanimously.

The report of the Anæsthetics Committee was similarly moved and adopted, which ended the proceedings for the day.

There was a musical promenade in the afternoon at the Gardens of the Royal Botanic Society, followed in the evening by an illuminate fête at the same gardens. This very popular entertainment continued until midnight. The Duke and the Duchess of Teck visited the gardens. On the lake there was a floating windmill, the body constructed of bright red lamps and the sails white, and a very effective attraction it proved to be. In the large tent there was a great display of medicinal and tropical plants geographically arranged, and the bands gave great delight to the lovers of music.

Third Day, Thursday, August 1st.

The Address in Surgery was delivered by Mr. Jonathan Hutchinson, who was received with loud and prolonged applause. He paid a graceful tribute to the memory of Mr. Arthur Durham, whose untimely death threw the duty of delivering this address at somewhat short notice on his shoulders. It would perhaps be of advantage to take a brief retrospect of surgery, without going back beyond the last century, but he could not attempt to compete with Sir William Broadbent, whose retrospect of medicine must be fresh in their minds.

In the year 1750 Samuel Sharpe published "A Critical Enquiry into Surgery." The author was a fellow of the Royal Society and a surgeon of good position in his day, and he prepared himself for his task by travel and inquiry on the Continent, where he observed and studied foreign surgery, and this work indeed was the result of a visit to Paris. It was received with favor and translated into French, German, and Spanish, and may be taken as affording a fair criterion of the state of surgery at that time.

Sharpe thought well of English surgery. It is to be remembered that Pott was then in his prime and John Hunter still young. As to the treatment of fractures, Sharpe says that of course all surgeons were agreed as to their treatment. In reading his book one is struck by the restriction of topics, in marked contrast to the vast field covered by surgery now. He remarked of

one operation that it was "neither dreadful in the doing nor melancholy in the event," and it would seem that the contrary was true of many of the operations then in vogue. More than sixty years afterward a French surgeon named Roux published in Paris the results of his observations made in London. These were the days of Astley Cooper and Lawrence, and John Hunter had been dead for twenty years. He noted what he considered the extraordinary fondness of English surgeons for anatomical preparations. He held the opinion that England was the only rival of France in surgery, other nations being beneath notice. Russia was then only emerging from barbarism, and the surgery of the United States, which has of late years so largely contributed, and bids fair to more and more contribute, to our knowledge, was scarcely in existence. He noted also that only one hospital in London, and that the speaker was proud to say was the London Hospital, made any attempt to distinguish between medical and surgical cases. In some cases he criticised adversely the dexterity of the surgeons, and remarked that twenty minutes was the time taken to perform a circular amputation, an operation which the Paris surgeons would have completed in a quarter of that time. He thought also that fractures were treated better in France than in England. Roux was amazed to find so much time, labor, and money expended at the College of Surgeons Museum on comparative anatomy, a subject that he thought should be treated in a museum of natural history. What would he say could he revisit the museum now and find our best wall space given to collections of skulls and other non-surgical specimens? We have turned what should be an unrivalled clinical museum into a Golgotha of anthropology.

In the year 1854 Mr. (now Sir) Spencer Wells was editor of the *Medical Times and Gazette*, and the present speaker was his assistant. Believing that contemporary medical literature but imperfectly represented the real results of operative surgery in London, he instituted a systematic inquiry, which was largely conducted during three years—from 1855 to 1858—by Mr. Hutchinson. In the course of that inquiry he learned much. He frequented all the operating theatres of London, and was in confidential communication with many surgeons. In some cases the results were surprising.

Spencer Wells and Hutchinson thought at one time that ovariotomy was an unjustifiable operation. They knew of fourteen consecutive cases, all fatal; and indeed a well-known coroner announced his intention to hold an inquest on the next fatal case that came under his notice. The results of lithotrity also were most discouraging. Cases were reported cured, but they were not cured; they turned up again and again, and became perennial patients. The published reports on the operation were most untrustworthy. This was before the work of Bigelow had entirely revolutionized the treatment of stone, but when litholapaxy was introduced he recognized the fact that the days of lithotomy as regards most cases were numbered. He had taken up the operation warmly, but finding that he could not get the amount of practice needful for the education of his hands, after one fatal case he refused again to operate and handed over those cases that came to him to specialists. He had done this in many cases, including two of his own colleagues. For many years now there had been no death from the operation as it had come under his notice, and no case had required a second operation. It might well be said that relief was "cito et tutum." It was in the hands of specialists that this great success occurred. He considered his practice of lithotrity through the hands of others most successful, and was proud of it.

Spencer Wells did his first ovariotomy in February, 1858, and the speaker followed with one in May of the same year. Both were successful. Baker Brown, who had some years previously had successful cases, was present at both operations. At that time the treatment of the pedicle was a burning question. The extra abdominal method commended itself to him, and for its better carrying out he had introduced the clamp, with gratifying results. Spencer Wells, however, ligatured the pedicle and dropped it back, leaving the long ends of the ligature hanging out of the wound. The latter's first case suppurated, perhaps owing to the ends of the ligatures in the wound. Finding that his cases in the wards of a general hospital, where sufficiently strict precautions could not be taken, did not do so well as those under Spencer Wells, he gave up operating and sent all cases to the Samaritan Hospital, acting on the principle that it would be wrong to undertake an operation himself that he thought could be better or more safely performed by another. After a time the clamp, which at one time bade fair to become a permanent addition to the surgeon's armamentarium, was discarded, and the pedicle generally dropped back into the abdomen. Tyler Smith was one of those who made this method popular. It was difficult to understand why a proceeding that is so successful now should have been so unsuccessful formerly. Probably the increased knowledge of the principles of antisepsis and asepsis was the cause.

Specialism in eye disease had proved of the greatest benefit. When Roux visited London he remarked with disapproval on the special ophthalmic hospitals which were springing up. He thought them likely to injure the best interests of the profession and the public. Years afterward when the speaker visited Paris he saw the results of this prejudice in the wards of Roux's own hospital, where in case after case of cataract extraction the eye was lost through suppuration. He believed that if the statistics of ovariotomy for the whole kingdom could be collected they would be found to be far less favorable than the statistics of specialists.

Many men, such as Sir H. Thompson, in bladder surgery, Macewen, in brain operations, and Mayo Robson, in the surgery of the gall-bladder, while unconnected with any special institutions, were yet specialists. These were instances of what we might call personal specialism, and these men were benefactors of the public, and a striking feature of their practice was that they had an influence over and trained others in those special branches. The evils of specialism were known to all, but charlatanism was not confined to specialists by any means, and it was in the early days of a specialty and before it was well established that charlatans found their opportunity.

Suppose that at the present day a journal were to follow the plan of Spencer Wells and himself in 1855, the results would be astonishing. The increase in the number of operations both in public and in private practice was enormous. He could remember the institution of the first nursing home in London, and a very humble beginning it was. Now there were streets where every other house was a nursing home, and each equipped with a staff of admirable nurses, who seemed to be born for their calling. What became of such women before the modern nurse existed he knew not, and he was equally at a loss to know what became of these nurses nowadays, for none of them ever seemed even to approach middle age.

The use of anæsthetics had enormously increased. It was not so very long ago that one practitioner only was enough for the needs of all London, and some surprise was expressed that he should find enough to do. Mr. Snow was succeeded by Mr. Clover, and although his monopoly was less absolute, still for a long time he had no rival. To-day there were names of no less than six official anæsthetists on the list of the staff of Guy's Hospital alone. And there was a society of anæsthetists which had found it necessary to refuse to admit any but *bona-fide* specialists. He would here refer to the wonderfully complete and interesting museum of

anæsthetic apparatus exhibited in connection with this meeting.

The change in the last twenty years in the sentiments of the public toward operations was a very striking one. Formerly the surgeon had to persuade the patient to consent. Now he was in danger of being persuaded to operate, against his better judgment, by the importunities of the patient. It was recorded that each ancient Greek physician used to be accompanied in his visits by an orator, whose business it was to persuade the patient to take his medicine. No such persuasion was now needed with the improved pharmacy of to-day. He often wondered, if the physician needed one orator, by how many the surgeon had to be surrounded in order to be allowed to operate?

Surely no one ought now to die of cancer of the tongue. The awful mortality of other times was due to the neglect of attention to the early stages of the disease. A symptom which used to be relied upon, and taught as a valuable one for diagnosis, was that of enlargement of the glands. This, which in Syme's time was considered as an indication that operation was needed, would now be considered as rendering operative interference almost hopeless. He remembered to have seen Syme do his operation, dividing and everting the halves of the jaw, with his customary dexterity. The operation was, indeed, "dreadful in the doing and melancholy in the event." He thought that surgeons even nowadays, erred in not plainly telling patients as soon as they suspected it, that they had cancer. It would be found that they would submit to early operation. There were surgeons now who could boast of scores of cases of partial or complete removal, with little or no fatality. Formerly the horrors of long suppuration and many painful dressings deterred patients from submitting early to removal of the breast, although the operation had long been a successful one. No one would now wait for enlargement of the glands; and retraction of the nipple, formerly mentioned as an important diagnostic sign, would now be considered as evidence that interference had been too long delayed. The evidences afforded by the finger of the trained observer were enough, and it was now the rule, "when in doubt, operate." Patients had got to know that operation and subsequent recovery were almost painless, and submit gladly to early performance. The statistics of the operation must be rewritten. Recoveries without recurrence were not uncommon.

As regards the training of surgeons—in London recently a five years' curriculum had been made compulsory. Although he supported with his vote the measures concerted by the two colleges for carrying this into effect, he was not a warm advocate of it. It seemed to be an application of the argument, "If you keep a horse long enough at the water you can make him drink." We might exclude poor students who could not afford so long a time, and by a five years' curriculum John Hunter might have been shut out. In arbitrary enactments of this kind he had little faith. He would, however, reform the methods of examination. More time was wanted and more quiet opportunities for the candidate to do his best. Many a nervous man was disconcerted on entering the examination-room by the examiner suddenly thrusting some specimen at him with the challenge, "Tell me what that is?"

It was a mistake to suppose that medical education ends with the attainment of a diploma. There were plenty of general hospitals that invited the lad from school or college and provided for his professional education until he was qualified. He hoped that some day some general hospital would reserve itself for the teaching of the qualified men. Some operations should, he thought, be avoided altogether, except the skilled diagnostician and the skilled manipulator were at hand.

In conclusion Mr. Hutchinson said that the object of his address had been to attempt to grasp clearly and without prejudice the tendency of modern surgery. We must always remember that our first duty was to our patient, and that his claims were even greater than those of science. He referred to the tendency of improvements in surgery to damage the pecuniary interests of the profession. The public ought to appreciate this.

We might all be most thankful for the progress made. A hearty vote of thanks to the speaker was carried by acclamation.

The Patrick Stewart Prize.—Sir J. Russell Reynolds then presented the Patrick Stewart Prize to Brigade Surgeon Lieutenant-Colonel Cunningham (*in absentia*) for his valuable work in bacteriology, especially as regards the comma bacillus. He had also made important observations as to the temperature of the soil, and its bearing or the prevalence and activity of cholera. His works adorned the scientific literature of India and this country.

Fourth Day, Friday, August 2d.

Address in Physiology. — Dr. Edward Albert Schäfer began his address by stating that he had selected a definite subject upon which to address the meeting, namely, the internal glands, which were organs that secreted something from the blood, which had a considerable part to play in the economy of the body. The external secreting glands might also be called internal, for while they excreted they also passed secretions into the lymph or blood, but the ductless glands had only an internal secretion, and this was of more importance than the external secretion; in the case of the pancreas there was an excretory duct, and yet if this organ was removed from an animal, that animal would die. But if it was only partially removed, the creature would live. Removal of the kidneys was quickly followed by the death of the animal that had been deprived of them, and if only partially destroyed, the animal would live. They should, therefore, be ranked with the liver and pancreas as internal secreting glands.

The internal secretion of the liver was of two kinds, one of which was useful, and the other not so, and this was also the case with the kidneys; but the salivary and the mammary glands could be removed without any ill effect ensuing. The pancreas was structurally different from the other glands, for it contained within it portions of vascular epithelium scattered through its other tissues, and its sole use was not to secrete pancreatic juice. Twenty per cent. of diabetic patients suffered from disease of the pancreas. In 1845 C. Bernard removed the pancreas from an animal and it died a short time afterward, but on a subsequent occasion the operation was performed under more favorable conditions, and then glycosuria and polyuria appeared. The animals wasted and died in about fifteen days after the operation, but if a portion of the gland was left there was no diabetes; if a part of another pancreas was grafted into the skin of an animal and its own pancreas was removed, that was sufficient to prevent the diabetes, which appeared as soon as the graft was taken away.

Paraffin had been injected into the pancreatic ducts, which it destroyed. Atrophy of the organ followed, but no diabetes, for the islands of vascular epithelium were left intact, and to that fact the non-appearance of the glycosuria was due. The injection of pancreatic juice into the veins prevented the diabetes, but the operation was a dangerous one; raw pancreas administered by the mouth had no effect—had no influence.

The ductless glands had no external secretion, but nevertheless were secreting organs, for removal of the thyroid gland resulted in speedy wasting and death, as when that gland was extirpated for the cure of goître the operation was quickly followed by myxœdema. Mr.

Victor Horsley had operated on monkeys and found that they lived longer afterward than dogs did; when the operation was performed on birds no result followed, and herbivorous animals seemed to suffer little or no inconvenience from the removal of the thyroid gland, with the exception, however, of the rabbit.

The ill effects following the removal of the thyroid might be prevented by the administration of thyroid extract either subcutaneously or by the mouth, and a successful graft of thyroid effected a complete cure; in those cases where death ensued the subjects were thought to die from auto-toxication, the thyroid gland collecting material from the blood and converting it into a useful or at least a harmless product.

The pituitary body is a gland with an internal secretion, and its destruction is followed by death in about a fortnight, generally from an attack of dyspnœa; when the thyroid gland was removed the pituitary body was found to enlarge, but disease of the latter was not followed by myxœdema but by acromegaly. Injury of the pituitary body caused a rise of the blood-pressure, and a contraction of the blood-vessels. When the suprarenal capsules were removed, death from great muscular weakness quickly followed, but there was no deposition of pigment, which took place when they were injured or diseased.

Extract of suprarenal capsules produced no effect when injected into a dog, unless the dose was large. Rabbits are more susceptible. The intravenous injection of their extract showed that the suprarenal capsules yield a secretion of great power over the auricle, and that this effect was not due to nervous irritation was proved by its having the same effect in a frog from which the whole of the brain and spinal cord had been removed; but the effect soon passes off, though the reason for its doing so is doubtful, probably the product, whatever it may be, becomes stored up in the muscles. A very minute dose will produce the effect, a dose of one-millionth part of a grain will suffice.

Internal secretions are produced by the ductless glands as well as by the external glands. There is a vast field for the employment of these extracts, but much connected with them is still very obscure, and in all probability they are destined to take the place of vegetable remedies.

Professor Bowdich proposed a vote of thanks to the lecturer, and said that so far the employment in medicine of these animal extracts had not found much favor with the profession or the public, for they recalled to mind the barbarous remedies of the middle ages, when portions of animals were blended with vegetable and mineral products into a hodgepodge that was then thought to be a cure for every malady under the sun.

Professor Lauder Brunton was happy to second the vote of thanks, and thought that we have now come to the parting of the ways between the old and new therapeutics.

A vote of thanks was then put by the President, and carried with acclamation.

Professor Schäfer, in reply, would make but two remarks; he greatly appreciated the high honor that was conferred on him when the Council asked him to address the meeting, and also because of his election as the successor in giving the address in physiology of two such distinguished men as W. Sharpey and B. Saunderson.

The Secretary of the Association then read a resolution condemning the action of the Medical Aid Society and an expression of opinion that no one who accepted the position of medical officer to it should continue a member of the British Medical Association, which ought to have power to control practice of that kind.

The usual votes of thanks to all who had contributed in various ways to the success of the several meetings, and the pleasure and comfort of the associates, were then passed with the usual unanimity and applause, some amusement being caused by the President's allusion to the Colleges of Physicians and Surgeons, whose favors he remarked were yet to be bestowed.

New Instruments.

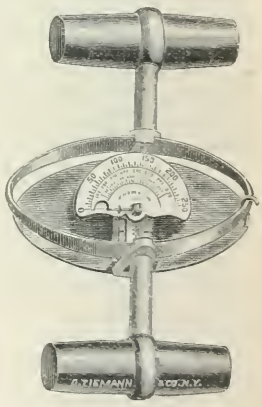
HOLDERS TO USE WITH THE HAND DYNAMOMETER.

By ALFRED J. ANDREWS, M.D.,

BROOKLYN, N. Y.

I have used these holders in testing several hundred cases during the past few months, with so much advantage and satisfaction that I feel that others, engaged in similar work, may find them useful. Until I had them made for me by Messrs. Tiemann & Co. I did not secure as much accuracy as I desired in the examination of the candidates for positions in the civil service of Brooklyn, and had no means of accurately measuring deficient or defective groups of muscles on either side of the body in other cases.

The hand dynamometer is placed in the frame, dial outward, and is held in position by the traction on the handles. In some tests both handles are held by patient, in others one is held by the operator and the other by patient (or other may be affixed to a hook in floor or wall), or in the "push" holder one handle of it may be applied against any portion of patient's body, while the other is held by the physician; in still other tests it is necessary to have a strap with a hook, as in testing the muscles of the neck with the "pull" holder, in which case it is also necessary to prevent the patient from influencing the result with his weight.



I have found these tests useful in recording the progress in tabetic patients, in saturnine poisoning and nerve injury, and have used them in testing the following groups of muscles with "holder for pulling:" Flexors of arm, of forearm, of leg, of foot, and of head; also the abductors of the arm (in different directions) and of thigh. The extensor groups, as those of forearm, of arm, of leg (quadriceps extensor)—these while seated—of head and of foot (with strap).

The "holder for pushing" may be used to supplement some of the above tests and for adductors of arm (pectorals, etc.), flexors of thigh, adductors of thigh, and of arm while forearm is flexed, elbow at side, and holder is between inner side of patient's arm and physicians' hand, which is on patient's side, and may also be used in testing power of muscles which raise hand from shoulder straight up above head (part of trapezius, deltoid, serratus magnus, triceps, etc.).

And lastly the pulling frame may be used for testing the accuracy of the dynamometer itself, by hanging it from a hook and applying carefully a known weight.

Insomnia.—If the patient is unable to obtain sleep during early hours of night, give trional; if patient readily falls to sleep upon retiring, but awakens too early, give sulfonal.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE WOMEN'S PETITION TO THE COLLEGE OF SURGEONS—UNIVERSITY OF DURHAM—GENERAL ELECTION AND MEDICINE—HONORS FOR SURGEONS AT CHITRAL—MEMORIAL TO HUXLEY—SMALL-POX IN THE SALVATION ARMY SHELTERS—CHELSEA HOSPITAL—PTOMAINE POISONING—A MEDICAL MOVE AT THE GENERAL ELECTION—SANITATION AS A PARTY CRY—ANOTHER HOSPITAL PROPOSED FOR LONDON—THE PRINCE AND PRINCESS AT THE ROYAL FREE HOSPITAL—THE SUNDAY FUND—THE DROUGHT—A FATAL PRACTICAL JOKE—BRITISH MEDICAL ASSOCIATION MEETING—BRITISH MEDICAL ASSOCIATION—MEMORIAL TO HUXLEY—ANOTHER TO MEYER—PRESENTATION TO SIR J. LISTER—DEATH OF SIR J. TOMES—HEALTH OF LONDON—OUTBREAK OF SMALL-POX.

LONDON, July 19, 1895.

THE school of Medicine for Women has taken what some think a bold step in petitioning the Council of the College of Surgeons to admit women to the examinations. The Council has never been considered a body likely to entertain such a proposal, it has always displayed conservative, if not to say, obstructive, instincts. I hear, however, that the ladies are very hopeful, and it is whispered in some quarters that influence has been brought to bear on individual councillors which justifies the expectation of success. There are councillors who are known to have supported the women's school, and it is hardly likely that they would not be willing to admit its pupils to any examination. Then there is the pecuniary aspect of the question. The Council is not likely to be indifferent to this. The fee for membership is twenty guineas. If other authorities admit women, why should not the college secure its share of qualifying fees. The college is the authority most generally known, its members being the most numerous, and if its doors should be opened to women no doubt they will crowd into it. The popularity of the diploma would secure a large proportion of the female candidates. How far the present members might approve the intrusion of further rivals is another question. But they will have no voice in the matter. The Council will decide. Having decided, it may mention the matter in the report to the meeting of fellows and members, but that meeting would be unable to reverse the decision.

In connection with this subject, I may state that the University of Durham has obtained a supplementary charter which enables it to confer on women any degrees it can confer on men (except degrees in divinity). One lady has already received a degree in science, and medicine, arts, literature, and music will no doubt soon have women graduates in their several faculties.

We are in the midst of a general election, so political controversy and excitement is displacing many medical subjects. This excitement is very injurious to certain weak or nervous persons, and three deaths are already reported as having occurred from this cause. A medical man was also assaulted in Cork, a rare circumstance even in that lively locality, for even turbulent Irishmen generally respect the doctors, to whichever party they belong.

That coveted distinction, the Victoria Cross, has been conferred on Surgeon-Captain Whitchurch for his conspicuous bravery during the sortie from Chitral Fort. Your readers will no doubt remember how he carried Captain Baird on his back through a hail of bullets, for the story has been told by all the newspapers. Surgeon-Major Robertson has been promoted to a knight commandership of the Star of India, and further honors will no doubt in due time be gazetted.

There are, I believe, not one hundred and eighty Victoria Crosses living in all arms, and the bronze medal and red ribbon being so seldom conferred, renders the distinction more coveted than perhaps any. Dr. Whitchurch makes the number of medical men who have won this honor up to fifteen now alive. This is certainly a splendid proportion, and should put to shame the snobs who sneer at the army surgeons as "non-combatants."

The memorial to the late Professor Huxley at Charing Cross Hospital is to take the form of a scholarship and medal, and if funds permit an annual lecture on recent advances in science and their bearing on medicine. It is not improbable that a memorial of a wider, perhaps national, scope may also be raised. In the meantime the Charing Cross School may be congratulated on the probable success of her attempt to honor her distinguished son.

Several more small-pox cases have been traced to Salvation Army shelters, but the managers of that organization still resist the proposal to place them under sanitary supervision. One medical officer of health went to inspect a shelter in his district with a couple of his inspectors, but they were refused admission. Dr. Waldo, the medical officer of health, obtained a justice's warrant, but was again refused until he threatened to bring a force of police. On this he was admitted and found overcrowding of the grossest character along with utterly inadequate ventilation. The vestry has ordered an abatement of the nuisance, and it is to be hoped that a firm determination to subject so dangerous a plague spot to the sanitary authorities will be maintained. No one wishes to interfere with the charitable work of the Salvation Army, but it is monstrous that it should be permitted to sow small-pox in the community. "General" Booth may be as autocratic as he likes over his willing "soldiers," but he must submit to sanitary laws, and if there is any difficulty as to the process of compelling him legislation must be called in. To set up a focus of infectious disease under the name of charity is too great a demand on the tolerance of the community. It is a great pity that the promoters of many a good work should be so obstinately blind to the evil of spreading infectious disease. There are able medical men among the supporters of the Salvation Army, and they would do well to speak plainly to the autocratic rulers, and if not listened to, they had better separate themselves from the organization and let the public know why.

It is whispered that further trouble threatens the Chelsea Hospital for Women. I hear that the chairman has asked for the resignation of one of the lately elected staff who refuses to comply with the request.

A sad case of poisoning, apparently by ptomaines, has occurred in a girls' school at Limerick, and four deaths have already occurred. This, too, just before the commencement of the holidays, when children and parents were looking forward to a happy meeting. A custard was suspected, and the cook had noticed that one of the eggs was discolored. Either that or the milk seemed to be the source of poison. Sir C. Cameron has investigated the matter and found no ordinary poison in the viscera of two of the patients. He, however, extracted a substance that gave all the reactions of ptomaines, but the quantity was too small to permit of differentiating this from other ptomaines. It is most unfortunate that none of the custard was preserved, nor of the vomit of the patients, as no doubt Sir C. Cameron would have been able to shed still more light on the matter. I believe this is the first instance in which a ptomaine has been extracted from the viscera of a person so poisoned.

LONDON, July 26, 1895.

IN the turmoil of the general election the doctors of Bradford, led by their distinguished Medical Officer of Health (Whiteside Hime), have scored well for their

profession. They submitted a series of questions to the parliamentary candidates in their locality as to the relations between the state and medical men. The pith of their queries was whether it was right for the state to exact forced labor from one class of citizens; and considering medical men acquire their knowledge without one farthing of aid from the state, and are not protected in practice as the lawyers are, ought they to be compelled to give gratuitously the result of their labors, whether by notifications, certificates, or otherwise?

The liberal candidates made only vague replies, no doubt remembering that their leaders when in power have always slighted the profession. The conservative and labor candidates gave straightforward and satisfactory replies. The result is an object lesson to politicians as well as doctors, for Bradford returned three unionists to parliament; and although the wave of public disgust which has made a clean sweep of the separatists had much to do with it, the influence of the profession must also be reckoned, and when it is remembered how wide-spread that influence must be if united, perhaps legislators will give some attention to representations as to the rights and wrongs of so important a class of electors.

Disraeli, when leading the victorious party, raised the cry "*Sanitas, sanitas, omnia sanitas.*" If now this party, which has come in almost unpledged except to maintain the union of the empire, will at once take up the great sanitary questions on which the welfare of the public so much depends, we may cry in the same way: *Magna est sanitas et prævalebit.*

It seems we are to have another general hospital in London. The cry is the need of such accommodation south of the Thames. No doubt that district is comparatively poor, but it has done hitherto without the proposed two hundred beds, and north of the river there is a sad superabundance of hospitals. It was proposed that Charing Cross Hospital should sell its enormously valuable site and remove to the poorer locality, but the managers repudiated the proposition. Yet it would have been an honorable action and have benefited north and south alike. Will no other hospital take the hint? Something depends on the tenure of their sites. I suppose the Westminster does not hold on sufficiently favorable terms, or one could well spare it, and to place some unprejudiced gentlemen of the south on its board would perhaps neutralize the unjust treatment it has too frequently measured to its staff. If this new hospital is to be established it would be a blessing to confine it to in-patients, and so prevent any further abuse of the out-patient department of hospitals.

The Prince of Wales, with his wife and daughters, opened the new buildings at the Royal Free Hospital on Monday last, referring gracefully in his speech to the interest taken in the charity by his family. The new front building, which has cost about thirty thousand pounds, is named after the Princess Alexandra, and after the ceremony Her Royal Highness passed a considerable time in the wards, speaking a few words to the patients and distributing among them the flowers of the bouquet which had been presented to her.

It is expected that the Hospital Sunday Fund will this year amount to £46,000, and the Lord Mayor is appealing to the public to make it up to £50,000.

The long spell of fine weather has threatened some districts with a water-famine. Proceedings have been taken against one of the London companies for not supplying the amount necessary to householders. It is strange that this should be considered less urgent than the watering of the streets. In some rural districts, also, the drought has caused suffering and brought into prominence defects which the sanitary authorities must remedy, or great danger will be incurred.

A sad death has followed a stupid practical joke. The joker tickled a sleeping man's ear with a wooden spill. A sudden start, a splinter penetrating the tympanum, inflammation spreading to the brain, inquest! Such was the course of events. When will these practical jokers cease their foolish annoyances?

The British Medical Association is to occupy us in London next week. Some ominous grumblings have been heard as to the rejection of papers in some sections. Some discontent has also been manifested at the pressure put on leading men to prevent them giving their communications to other journals. The editor has inserted a black-letter notice that applications for copies must be addressed to him. All in editorial order, but I remember some years ago he managed to comply with such requests when it was too late. As I don't want copies I can express the hope that those who do may succeed in getting them. Still it savors of littleness that "this great association," as the clique love to call themselves, should try to dictate to authors who make the meetings attractive.

There is likely to be a regular scrimmage over the midwives question, which is exciting controversy in all directions. A meeting has been called for the night before the association meets, and notices of amendments to the proposals of the Council have been given. So at least one lively general meeting is possible.

London, August 3, 1895.

The British Medical Association has occupied us this week, and what with address and speeches, most of us are glad it is nearly over. Then dinners, luncheons, and similar functions have surfeited many, and the rest of us have devoted ourselves to making our guests comfortable.

The President opened with a dinner on Monday, when he was still President-elect. The same evening there was a meeting of the opponents of the Registration of Midwives, outside the association, and against the policy which the *Journal* clique has so unjustifiably tried to push. The profusion of entertainments will have given our provincial brethren a great variety of choice, and most of them seem to have been well pleased at our efforts to please them. There were almost necessarily some shortcomings and omissions, but they will doubtless be forgiven.

To-day is to be devoted to excursions and entertainments as usual, and yesterday not a few of our guests bid us farewell. Some of us will follow their example to-night and leave the metropolis for a holiday, which unless snatched at once will be lost altogether. Meantime your own reporters have sent you full accounts of each day's proceedings.

Memorials and testimonials have been much to the fore during the week. It is proposed to raise a national one to the late Professor Huxley, and the Royal Society has taken the necessary steps to constitute a preliminary committee. No definite action further than receiving names of those intending to subscribe will be taken at present, but after the holidays the adherents to the proposal will be asked to elect a committee to replace the temporary one and to carry out the wishes of subscribers in the matter.

A memorial is being got up to Wilhelm Meyer, whose pioneer work on adenoids in the naso-pharynx is everywhere recognized—so a committee has formed itself in London. These gentlemen have appealed to the public in a letter to the newspapers about the thousands of persons "saved from life-long deafness," and so on. I don't admire the taste of the letter, deeply as I would honor Meyer, but as the presidents of the two Royal Colleges have signed it, I have no opposition to offer.

There was a large gathering at King's College Hospital on Tuesday, to present to Sir Joseph Lister a portrait of himself. The presentation was made by Sir J. E. Erichsen in very felicitous terms. Among other appropriate remarks Sir John said a new era had come, old methods had been swept away, and new ones taken their place in the daily practice of surgery, and the great change was undoubtedly due to the antiseptic

system, and that boon constituted Sir Joseph Lister one of the greatest benefactors of mankind. Antiseptic surgery had become almost painless, mortality from operations almost extinguished, and the domain of surgery immensely increased. He did not undervalue anæsthetics, but it was a fact that during the twenty years between the introduction of anæsthetics and that of antiseptics, mortality had actually increased. Nor did he undervalue sanitation, but it would be easier for antiseptics to dispense with hygiene than for hygiene to dispense with antiseptics. All this they owed to the genius and untiring labor of the great surgeon sitting by his side and to him alone. The discovery of antiseptics was no haphazard affair, but was worked out laboriously on scientific lines. He placed Lister beside John Hunter. What one did for the end of the eighteenth century, the other did for the end of the nineteenth. It was fitting that the first testimonial should be within the walls where so much of the work had been done, and perhaps not unbecoming that he himself, who had been Sir Joseph's earliest teacher of practical surgery, should have been asked to present it to his dear friend and former pupil. Though they once stood in that position it had long been reversed, and for twenty years past he had been content to sit at the feet of his former pupil.

Sir Joseph Lister said he felt overwhelmed by Sir John Erichsen's kind and flattering words, and the great gathering of former pupils and colleagues. He could not deny that the presence of so many old friends was a great gratification, and showed his work had not been in vain. He gave an account of his work in Edinburgh, Glasgow, and London, which was listened to with profound attention.

Sir John Tomes, F.R.S., died on Monday at the age of eighty years. He was the pioneer of teaching modern dental surgery, his lectures at the Middlesex Hospital, begun fifty years ago, at once stamping him as an authority. His papers presented to the Royal Society established his reputation as a man of science, and his name is indissolubly connected with important points in the structure of the teeth. For his services to dental education he was knighted in 1886. Three years previously he and his friend, the late Professor Huxley, were elected to the Honorary Fellowship of the Royal College of Surgeons.

Last week the London death-rate fell to 23, as against 22.5 in the other large towns. Measles and diphtheria showed an increased mortality. The deaths from diarrhœa reach 397, which number is 137 above the corrected average.

Small-pox too has increased to such a degree at the East end of London that the Local Government Board have re-issued their 1893 circular urging Poor Law Guardians to take precautions against the spread of the disease through casual wards and workhouses. There is no doubt the danger is great and largely through the folly of anti-vaccinationists. Just where these cranks have deluded the most ignorant of the population into repudiating vaccination small-pox has made its appearance. In 1891 the official report showed that in one district (Mile End) half the children born were not accounted for in the vaccination returns. There has probably been no improvement since, and yet the local authorities are recalcitrant. Some method of compelling them to discharge their duty must be found, or the vaccination acts will be practically repealed in certain districts to the peril of others.

Medical Politicians in France.—In the French Senate thirty-seven senators are medical men, one senator is a druggist, and three senators are veterinary surgeons. In the Chamber of Deputies, fifty-eight deputies are medical men, five are druggists, and one is a veterinary surgeon.

RECIPROCITY IN REGISTRATION.

To the Editor of the Medical Record.

Sir: Allow me to make a few remarks in regard to reciprocity in registration.

1. What is registration for? Is it understood in the same light as the registration of the Chinaman, that so many should land and no more, or was it meant for some higher purpose, viz., to protect the public from quackery, fraud, etc., and to protect the dignity of the medical profession, to elevate its standard, etc.?

I contend that the registration law was intended for the latter. Now let us see if it has accomplished its purpose. Let us consider what is reciprocity. It means acting in return, *i.e.*, if New Jersey will allow a New York physician, who has passed a satisfactory examination after four years' study in a reputable college, to register, then New Jersey physicians should enjoy the same privilege when they come to New York. Does the absence of this reciprocity not mean that registration laws were made for pecuniary reasons? Does the knowledge and the science of the physician cease at the border line of the State?

Why is it that a patent medicine, made after the formula of a physician, and claimed by its maker to be a panacea for all the evils that flesh is heir to, is allowed to flourish in the United States, although the formula is taken from say New York, and the same physician who wrote the formula has no right to go to New Jersey and prescribe it? Is there any reason for this discrimination? Is it not a disgrace to the profession and an insult to every physician?

Now let me point out the injustice of the registration law as it is at present. 1. A physician living in New York takes a vacation at the seashore of New Jersey; he meets his own patients there, but he has no right to prescribe for them, for he is supposed to have forgotten all crossing the Hudson.

2. A physician having complied with all the requirements of the law in New York, and unable to make a living there (as it is often the case), having spent all the money he had, has no right to go to Jersey or any other State unless he passes an examination and pays a fee. Is that justice? What is the remedy?

I suggest that the medical press, societies, and individual members should agitate the question of a Secretary of Public Health, and so do away with the red tape of the different States. One law for all physicians of the United States. The standard of medical practice should be high, but once the examination is passed the candidate should be allowed to follow his profession in any of the States. Of course there will still be the necessity of registration, but the permission to register will not rest within the discretion of any State Examining Board. Respectfully,

L. W. Zwisohn, M.D.

New York, August 3, 1895.

Suicide is not common in Russia, the rate being 30 to 1,000,000 inhabitants, while in Saxony it is 311, in France 210, in Prussia 133, in Austria 130, in Bavaria 90, in England 66; and while the rate has increased by thirty or forty per cent. in other European countries during the last thirty years, in Russia it has remained stationary. Professor Sikorski, of the University of Kiew, thinks the low rate is due, in part, to the patience and long-suffering of the Russian under even the worst treatment, but also to an indecision of character which fears to do anything from which it cannot retreat.

It should be mentioned, in the interests of antiseptic purity and suffering humanity, that a good stout tooth-brush, plenty of water, and some antiseptic dentifrice, applied morning and night, afford a greater safeguard against many diseases than many people are aware.—Sims Woodhead.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 10, 1895.

	Cases.	Deaths.
Tuberculosis	53	110
Typhoid fever	29	5
Scarlet fever	24	3
Cerebro-spinal meningitis	0	3
Measles	135	15
Diphtheria	138	28

Sewage Organisms and Disease.—In his reports presented to the London County Council Mr. J. Parry Laws, F.I.C., made the important observation that the micro-organisms contained in sewer air were not only less in number than the micro-organisms in fresh air in the vicinity at the same time, but that they were also apparently related to and derived from those of fresh air rather than sewage, while there was no evidence forthcoming that sewage was able to give off micro-organisms to the air in contact with it. Acting on the instructions of the Main Drainage Committee of the Council this investigation has since been extended by Mr. Laws, with the assistance of Dr. Andrewes, to a study of the organisms existent in sewage. From a copy of the valuable report which has recently been issued, and which contains a careful series of well-chosen and laborious experiments, *The Lancet* gathers the following: The most striking difference in the bacteriology of sewage and sewer air appears to be the absence of moulds from the latter, while in the former moulds were found to be a predominant feature. The bacillus coli communis was found, with one exception, in each sample of sewage examined, but neither it nor its allies were ever found in sewer air. The bacteria of sewage rapidly liquefy nutrient gelatine, while organisms possessing this property were practically absent in sewer air. This evidence would seem to be conclusive that there is no relationship between the organisms of sewer air and sewage, and the writers are thereby led to think that some of the ill-effects which have been erroneously (?) ascribed to sewer air may be due to subsoil air derived from soil polluted by constant infiltration of excremental matter, but suggest that it is not until the outer margin of the permeated soil has become dry that the air is infected with organisms. In a search for the typhoid bacillus in sewers, where it might be expected to be present in large proportion, such as in the drains of the Eastern Hospital at Homerton, they were successful in demonstrating the actual presence of the bacillus typhosus; but in a sample taken about a quarter of a mile away no single colony developing on culture could be referred to the bacillus of typhoid fever. In the light of this and other results it is concluded that sewage, even in the absence of the normal micro-organisms which it contains, is clearly an unfavorable medium for the growth of the typhoid germ, whereas the colon bacillus can grow and multiply freely in it. It might be anticipated, it is pointed out, that in competition with other organisms, able to grow well in sewage, the typhoid bacillus would die out even more speedily. These experiments are only preliminary and are necessarily incomplete, but they give a distinct indication of the probable fate of typhoid bacilli which gain access in a living condition to sewage, while it seems "clear that sewage does not form a medium in which much, if any, growth is possible for them under natural conditions, and their death is probably only a matter of a few days, or at most one or two weeks." Obviously, this resistance to growth may be overcome by attenuation, as when sewage has access to the drinking supply or to milk.

It would appear, then, that so far as bacteriological analysis goes there is no ground for believing that sewer air plays any part in the conveyance of typhoid fever; but are the conditions under which the bacteriological examinations of sewage and of sewer air are made such as to give us absolute assurance on these and other points? In spite of its apparent bacteriological innocuousness no one entertains the least doubt that sewer air is a constant source of disease, and if this is not to be referred to micro-organisms to what may it be ascribed? There is undoubtedly a poisonous agency at work when sewer air is inhaled, which, though it may not directly act, yet so prepares the soil that the system is unable to resist the invading organism when it comes. In some well-known experiments it was shown that when rats, among other animals, were inoculated with a weak growth of typhoid culture, after previously being exposed to sewer emanations, they nearly all succumbed. On the other hand, rats treated to the same dose of typhoid culture, but exposed to fresh air after inoculation, showed little sign of illness and eventually recovered. What, then, is this poisonous constituent of sewer air which leaves the system defenceless against the attacks of the microbes which it may encounter? An investigation on this point would form, we suggest, an excellent and fitting sequel to the above valuable contribution.

NEW BOOKS RECEIVED.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

CEREBRAL TUBERCULOSIS IN ADULTS.

BY JOHN C. KING, M.D.,

BANNING, CAL.

IN the February number of the *Southern California Practitioner* appeared a useful article by Professor Brainerd, in which he detailed four cases of cerebral tuberculosis. In each case the diagnosis was verified post mortem. Dr. Brainerd expressed the opinion that all such cases are fatal. He referred to the recovery of Dr. Solly's reported case, but doubted the diagnosis. I desire, at the risk of having my diagnostic ability questioned, to report one case—Case IV. of this series—of absolute recovery from cerebral tuberculosis in an adult; also several cases in which recovery from cerebral conditions occurred, followed, however, by death, after some months, from the ravages of the disease in other parts of the body. I am of opinion that tubercular deposits in or upon the brain are of more frequent occurrence than is generally supposed. Perusal of systematic works on practice would lead us to consider nervous tissue slightly, if at all, obnoxious to tubercle. This statement excepts, of course, the ordinary tubercular meningitis of childhood. During the past ten years I have observed more than a dozen cases of cerebral tuberculosis in adults, about two per cent. of all cases of tuberculosis under my care during that time. Of these I have preserved notes of eight cases, one doubtful, which I will present in this paper. For twelve years preceding the past ten, I was engaged in general practice—four years in dispensary service—yet during that time never recognized a single case. The symptoms of cerebral involvement are so prominent that "he who runs may read;" yet, judging the first twelve by the past ten years, I must have overlooked many cases. Possibly others fail to realize the import of these symptoms. Dr. Brainerd quoted some interesting statistics of the disease in children, and referred to Osler, Whittaker, Gowers, Dana, and others who have noticed it in adults. However, the paucity of the information to be obtained upon this subject from textbooks is very marked. I may be permitted to refer to the statements of a few authorities: Flint, in "Practice," 1868, declares that "meningitis occurs as a rare concomitant in the adult," and that it "accounts for the development of delirium and coma in certain cases." Ruehle, in Ziemssen, 1875, writes, "Whenever phthisical patients present decided symptoms of cerebral disturbance, it is safe to infer an extension of the tuberculous process to the brain. The occurrence, therefore, of a fixed headache, sudden delirium, or maniacal excitement, may be regarded as very ominous symptoms." J. Hughes Bennett, in "Reynolds's System," 1880, refers incidentally to the fact that, in the young, tubercle complications in the brain and its membranes may sometimes occur. Bartholow, in "Practice," 1882, does not refer to cerebral tuberculosis as a complication of the pulmonary form. Ingals, in "Diseases of the Chest," etc., 1892, states that "in the later stages of the disease, cerebral anæmia, or possibly tubercular change in the brain itself, or the sympathetic effects of imperfect digestion, affect the mental condition, causing irritability, fretfulness, cerebral fatigue upon mental exertion, and finally, in some cases, hallucinations or fixed delirium." Osler, in "Practice," 1892, refers to various forms of cerebral tuberculosis apart from tubercular meningitis. He instances hemorrhagic pachymeningitis caused by tubercle, aphasia produced by solitary tubercle of the fissure of Sylvius. He writes of aphasia and hemiplegia of many months' duration existing as tubercular complications of consumption. Loomis, in "Practical Medicine," 1892, states that "cerebral symptoms are rarely pronounced in any stage of phthisis." Later, discussing tubercular tumor of the brain, he writes that children are chiefly affected.

The following cases were not examined post mortem, but, except Case I., the symptoms of each were evidently the result of tubercular deposit in or upon the brain:

CASE I.—G. B——, aged twenty-seven, male, of Milwaukee, brewer, under my observation during a large part of the year 1885. Had pulmonary tuberculosis, but was doing exceedingly well, so that I could offer him much encouragement. His domestic and financial affairs were in excellent shape. The day previous to his death the young man came to my office complaining of headache; otherwise seeming quite well. He was cheerful, but his conversation was somewhat erratic. Early next morning I was called by a workman, who stated he had looked into Mr. B——'s window after having knocked at the door, and believed him dead. I took witnesses, went to the house, burst open the door, and found him dead. There was a bullet wound in his temple, the revolver lay upon the floor beside the body. Evidently suicide, and so determined by the coroner's jury. A note was found addressed to his brother and dated the night of the tragedy. This note was written in German, and the contents were incoherent. The man's life had been insured, with the proviso that death from suicide, except as a result of mental disease, would invalidate the policy. I swore the patient was irresponsible, basing my opinion upon a diagnosis of acute cerebral tuberculosis. The insurance company paid the claim.

The history I have presented is very meagre. I think, however, perusal of the following cases will, by analogy, justify the diagnosis:

CASE II.—Charles P. D——, aged twenty-five, of Black River, N. Y. First examined in the latter part of 1885. Died May 3, 1886. Diagnosis: Pulmonary tuberculosis. During the last week of his life Dr. Johnson, of San Diego, was in consultation. The patient was surrounded by all the comfort and care that friends and money could procure. Mr. D—— had a very fair family history. He had been a successful manufacturer, had created and managed a large and profitable business, far in excess of his physical ability. He gradually undermined his health and remained in control of his affairs long after symptoms of pronounced pulmonary disease became manifest. Finally he came to Southern California. Having been referred to me, he applied for examination. I informed him that nothing could be done for him, beyond the relief of certain distressing symptoms. This young man possessed a very serene, well-balanced, highly cultivated mind. He governed his thoughts and actions in accordance with most exemplary principles. His case

progressed without notable failure or improvement for some months. Indeed, he gained a little strength, ate pretty well, and spent his time quite comfortably in the open air. He lived in an elegantly appointed country hotel, half a dozen miles from my office. I visited the house every two or three days, but never detected any intimation of impending involvement of my young friend's brain. About the middle of April I was sent for to visit D——. When I arrived the landlady called me aside and stated that—she was distressed to say it—Mr. D—— had been intoxicated for twenty-four hours or more. She wished me "to straighten him up." I found him sitting upon the veranda, as I approached he failed to recognize me. I spoke and extended my hand. He arose, held out his hand, mumbled something and at once staggered back into his chair. He presented every appearance of acute alcoholism: face congested, half-silly, half-stupid expression, eyes bright and a trifle watery, muscles relaxed so that he half-reclined in his chair. To all my questions he replied "Yes," with a silly sort of laugh. He would respond to suggestions, would sit, stand, swallow, etc., as requested. At times he would even reply, for a moment, to some question, with apparent correctness, and then, perhaps before his answer was complete, would relapse into the semi-conscious state. At no time would he acknowledge pain, nor did he, at any time, complain of headache. He endeavored to walk and to undress himself, but his muscles seemed too limp. He seemed to lack both co-ordinating and muscular power. The good landlady attended him the more devotedly because she had misjudged his condition. For several days he remained in about the same state. The excretory functions were performed when he was so requested. Food and medicine were also taken when suggested. Finally his condition became worse; semi-coma and coma successively developed. Catheterization became necessary. There was no fever; heart and kidneys normal; respiration became slower and deeper than before; pupils normal; face became paler. There was no action of the voluntary muscles for some days, yet no tendency toward bed-sores. This condition persisted for five or six days, when improvement began. In twenty-four hours the patient was, apparently, as well as before the attack, except for profound prostration. During my absence from the house, Mr. D—— gave explicit directions regarding his business affairs and the disposal of his effects. Some hours after, he quietly died. He remained conscious to almost the end.

Case III.—Charles M——, aged twenty-eight, of Lamar, Mo. Mother, two brothers, sister, and aunts had consumption. Martin developed the well-known symptoms of the disease, and was advised to remove to Southern California. After arriving here his history was uneventful; the disease pursued its ordinary course, although its progress was slow. The patient was a laborer, had wife and children to support, consequently could not care for himself as he ought to have done. After watching his case for some two years, I was called to his bedside on September 8, 1888. I found him wildly delirious. The combined efforts of several men were required to restrain him. My first thought was "a drunk," notwithstanding I knew him to be a total abstainer. Investigation soon convinced me that his system contained no alcohol. His wife stated that except a severe headache, he seemed in his usual health until he began to "act crazy," when she sent for me. The patient exhibited the wildest mania. He struggled, fought, bit, raved, cursed violently and obscenely. He had been a consistent Christian. No other symptoms could be elicited. The terror and distress with which he inspired his family and friends allowed no time for examination. To prevent injury to himself and others I had him strapped to a comfortable cot, then administered hypodermics of morphia sulph.; two quarter-grain doses were required. Three or four hours sleep followed. When he awoke he was calmer but still delirious, and at intervals required restraint. During the ensuing twenty-four hours the mania very gradually disappeared and semi-stupor supervened. The patient would swallow nourishment placed between his lips; would attempt to answer questions, but his replies were absolutely incoherent. At the first observation his temperature was 104½° F., but within forty-eight hours became almost normal without the administration of antipyretics. Bowels and bladder were incontinent for two days. No involuntary motor symptoms were apparent. The stupid stage gradually disappeared after five or six days. As he regained consciousness the only symptom complained of was headache, which he could not localize and which gradually ceased as he grew more rational. No memory of his condition remained. The case was void of further symptoms; recovery was rapid. The lung trouble was in abeyance for a few weeks. M—— returned to work and for two months was able to earn full wages. In December he died from phthisis pulmonalis, without return of cerebral symptoms.

Case IV.—First examined July 16, 1889. Referred to me by Professor Ingals. Mrs. W——, of Chicago, aged twenty-seven, married four and one-half years; miscarriage two years ago at three months. Now has a baby three months old. Always delicate but never really sick until two years ago. When about eleven years old underwent a surgical operation upon her foot, for what was termed tuberculosis of one of the bones. No tubercular taint in her family. Husband healthy. Had, at one time, some slight uterine trouble—readily cured by local treatment. Following miscarriage had cough and diarrhœa. Tubercle bacilli demonstrated in sputa and stools. Emaciation began at about the eighth month of last pregnancy. Slight hæmoptysis during labor, in which she was attended by Professor Jaggard, who performed episiotomy and a primary operation for laceration. Has never recovered strength since birth of child. Menses recurred about six weeks ago; at present quite weak. Post-nasal catarrh. Throat dry, and at times painful; hoarseness; vocal cords relaxed. Slight arytenoidal swelling. Pretty constant, loose, painless cough; at times becoming paroxysmal and accompanied by vomiting. Expectoration profuse, thick, greenish yellow. Pulse, 120; temperature, 102½° F.; respiration, 19; expansion, 26 to 28. Cavity in the left apex. Subcrepitant râles pretty much all over remaining part of left lung. On right side dulness around and below nipple, with loud, moist râles all over front and back. Appetite fairly good. No gastric pain. Tongue clean. Diarrhœa. Stools changeable, profuse, mushy. Four to twenty per day. Normal weight 124 pounds; at present 97. Profuse night-sweats from time to time.

To transcribe my notes of this case would be tedious, as the patient remained under my constant treatment for two years. I will at once detail (and that rapidly) the cerebral symptoms that ensued after some months. The first point noticed was headache. The whole head was involved, but the severest pain was occipital, extending forward toward the eyes. This pain became exceedingly intense. The lady was very courageous, but was many times forced to cry and scream on account of the violence of the pain. It resembled the pain accompanying tumor of the brain. Owing to this pain Mrs. W—— was obliged to take to her bed, thus avoiding light, noise, and motion. Finally mental symptoms began to develop. A little flightiness became noticeable. Hallucinations developed, such as visions of rats, bugs, etc., on the wall and bed. Gradually torpor of mind became apparent, marked by slow and stupid replies to questions. Twitching of muscles appeared, followed after a few days by violent convulsions. No paralytic symptoms at any time. As the motor disturbance subsided the patient became calmer, evidently had less headache, but failed to recognize husband, sister, or nurse. She

imagined herself in another city, in short, exhibited the classical symptoms of an attack of insanity. This latter condition, after continuing some two weeks longer, finally wore away, leaving the patient apparently none the worse for her experience, beyond the natural prostration. The pulmonary and intestinal symptoms had already improved to a marked degree prior to the appearance of the headache. During the attack just detailed this improvement steadily continued and no relapse followed. At no time during the attack was fever manifest. Incontinence of urine and fæces occurred a few times. Liquid food was administered daily. Respiration was slow and regular.

When Mrs. W—— left Banning, some eighteen months subsequently, she was in excellent condition. No diarrhœa; weight, 120 pounds; very little cough; scarcely any expectoration; plenty of strength. To all appearance a strong, hearty woman. The cavity had contracted; except for a few râles the physical signs had disappeared. A letter from her husband, a few months ago, assured me that her improvement had continued, and that she was enjoying excellent health. I consider this case remarkable. I have had other patients who suffered from combined pulmonary, with cavities, and intestinal tuberculosis make good recoveries. No other one, however, in which these conditions existed, plus cerebral tuberculosis, has made such marked improvement. The five or six years of continued good health indicate the possibility of a final cure. This patient had all the advantages that love, wealth, and intelligence could bring to bear upon her case.

Case V.—One evening about 10 P.M. the proprietor of the Bryant House called me to examine a stranger. The patient, a man about forty years of age, came to the hotel, having arrived on the west-bound overland train. The man sat on a chair in the office until supper-time, about four hours. As he paid no attention to the announcement of the meal, Mr. W—— asked if he wished supper, the man looked at him but made no reply. Mr. W—— then touched him on the shoulder and invited him to the supper-room, the man arose without speaking and followed. Mr. W—— placed him at the table and was obliged to attend to other business. The waitress could not induce him to give an order. She supposed him intoxicated and brought him a meal of her own selection. The man ate, then remained in his chair until the waitress requested him to leave, at the same time taking hold of his chair. He arose and left the room without speaking. He returned to the office and took a chair. Later, Mr. W—— asked him if he desired a room—no answer. Realizing that something was wrong Mr. W—— sent for me. An examination made it evident the patient was suffering from pulmonary phthisis. I could not induce him to speak, or to reply by a sign. He had a stupid, half-dazed, half-inquiring expression; was free from fever; contracted his brows as if his head pained; presented no motor symptoms. The man had arrived without baggage; had probably left it on the train. The hotel register and a pen were offered him. He took the pen and wrote. The result was an unintelligible scrawl. There was nothing on his person that offered a clew to his name or residence. Mr. W——, the landlord, kindly cared for the patient that night and took him next morning to the county hospital at San Bernardino. Some months after I endeavored to trace the case. Meanwhile politics had reorganized the hospital staff and my inquiries were fruitless. Beyond question this case was one of cerebral tuberculosis.

Case VI.—First examined December 10, 1890. Referred to me by Dr. Arndt, of San Diego. William H. B——, of Ypsilanti, Mich. Tall, spare, blonde, aged thirty-three; teacher. Father, aged fifty-three; and mother, aged forty-three, died of phthisis. Health always excellent until the summer of 1889, when he took no vacation, worked at the Agricultural College all summer and entered upon his fall work worn out. In October he took cold, coughed, fainted in class-room; had some throat trouble; spat blood occasionally. In July, 1890, came to Southern California. First went to a small place in the mountains where he improved; but, wishing more contact with civilization, went to the coast, where he soon began to fail. Passing over the record of symptoms, which was but ordinary, I copy from my book the following data: Weight reduced from 163 to 136½ pounds. Pulse, 120; temperature, 102° F.; respiration, 24; expansion, 31 to 33½ inches. Larynx much congested; both arytenoids swollen and infiltrated, almost obliterating the space between. The patient complained much of laryngeal pain, but there was no ulceration. Right side of chest much flattened. Extensive cavity in right lung. The posterior portion of this lung was utilized for respiratory purposes, while the lateral portions were infiltrated. On the left side existed marked dulness at apex, and persistent moist râles audible all over front and back. Under proper care this patient gained perceptibly during the ensuing three months. Appetite and weight increased, cough and expectoration diminished, fever subsided, strength improved, physical signs were modified. However, about midnight of March 21st, I was called to his room; the noise he had made having awakened a neighbor. I found him in a peculiar dazed condition, sitting half clad upon the bed. The heart was beating 140 times per minute: temperature,normal; respiration, 14. His replies to questions were very slow, one or two minutes intervening between question and reply. Some of his answers were *à propos* and apparently rational, others bore no relation to the question. He would laugh in a silly manner and say he did not know what ailed him. Pain in the head, which he could not locate, seemed a prominent symptom. He seemed conscious of his surroundings and of his condition, but his remarks were erratic and disconnected. Next morning he came to my office in his usual condition. He wished to know what ailed him the preceding night, his memory of the events being clouded. The only symptom remaining was a dull, diffused headache. During the following month the patient was very despondent—contrary to his habit—and gradually lost bodily vigor. Yet the pulmonary symptoms improved. About 2 A.M. on April 18th, I was again called, to find him in a condition precisely similar to that of March 21st, except that he had fever, temperature 103½° F., and his mental hebetude was more profound. He would answer questions if urged, but his replies were *mal à propos*. The silly laugh, the vacant stare, the stupidity were peculiar. He had entire control over his voluntary muscles. There was no muscular twitching, but, at times, considerable restlessness. He would eat, if requested, or evacuate bowels and bladder; but did not seem to think of such things unless suggested to him. The fever subsided in a day or two, but the mental state remained. He looked like one in a dream, yet conscious when spoken to, or like a somnambulist. These symptoms continued, with gradually decreasing intensity, for two weeks. His mind became entirely clear and no trace of cerebral disease remained after three or four weeks. Mr. B—— returned to Michigan, where he consulted Professor Shurly, to whom I had referred him. I am ignorant of his further history until his death, late in the summer of 1892. I think he remained under the care of his brother, a prominent Michigan physician.

Case VII.—First examined January 28, 1893. Charles W. G.——, of Tacoma, student, aged twenty-two. Family history free from tuberculosis. Good health until February 1892, when he had la grippe. Was ordered to Southern California and sent to me. Present symptoms: Pain in larynx after talking. Cough, worse in morning and after exercise, but little at night, dry or loose, painful to throat. Expectoration scanty, freest in the morning, white, frothy, or yel-

low, at present bloody. Has had several hemorrhages during past fortnight. Some chest pain at bases of lungs, occasionally higher on left side. Sleeps on back or right side. Appetite good, but cannot use milk or fats. No flatulence, no abdominal pain. Gastric condition good just now, although he reports history of irritable stomach ever since illness began. Bowels regular until he commenced taking tannic and gallic acids to relieve hæmoptysis. Kidneys normal, no venereal; night-sweats have disappeared. Strength very limited. Normal weight, 135 pounds; present weight, 119. Extremities cold. Very nervous. Respiration, 36; pulse, 112, and weak; temperature, 100½° F. Hyperæmia of nasal mucosa, deviation of septum, hypertrophy of middle turbinated. Pharynx congested; follicular disease of posterior wall. Laryngeal mucosa red and swollen, presenting sodden appearance. Vocal bands approximate and are pearly. Arytenoids infiltrated, pyramidal. Right lung normal except slight retraction of apex. Left lung hepatized, some little air entering the infra-axillary, supra-scapular, and infra-clavicular regions. No cavities, but evidences of beginning softening. The pulmonary condition was probably the result of an unresolved pneumonia—tubercular infection having taken place later.

From the date of my examination the patient continued to improve until February 21st. On the 22d Mr. G.—— sent for me. He complained of nausea, pain in epigastrium, and headache. February 23d, patient reported a sleepless night, very severe frontal headache, inability to retain food, heavily coated tongue. Absence of abdominal tenderness, fever, etc., excluded gastritis. Indigestion of nervous origin seemed to explain the symptoms. The patient's mind was sluggish, his answers slow and hesitating—a condition I attributed to pain, loss of sleep, and lack of food. On February 24th the temperature was normal; pulse, 60, full and strong; abdominal pain moderate; no food retained; constipated stool; headache more general and severe; pupils dilated; mental state unchanged; very restless; complained of transitory numbness of left side. The possibility of tubercular deposit in the brain began to be considered. To reproduce the daily record would be tedious. From this time forward the manifestations of cerebral disease became more marked. The pulse continued slow—54 to 68—full and strong, until a few hours before death, when it became rapid and weak. Abdominal pain and nausea gradually subsided, so that, in a few days patient could take any easily digested food. Bowels remained constipated. Headache continued constant, always more severe in frontal region. Mental symptoms became more prominent by almost imperceptible degrees. At first merely slowness of cerebration, then confusion of ideas and statements, finally a dull, stupid state, gradually increasing into coma. The numbness was referred to one, then the other, and finally both sides—always transitory. Toward the end pupils became contracted. The restlessness developed into twitching of muscles, more marked on the left side. At times he was a trifle difficult to control. There was retention of urine for a few days, necessitating use of catheter. From the first the respiration was affected, the rate having fallen from over 30 to 16 or 18. The immediate cause of death seemed to have been inhibition of the respiratory functions. Death occurred March 5th, the thirteenth day.

Case VIII.—March 16, 1895. In response to a telegram I arrived at Indio at 2 A.M., and found my patient unconscious. The gentleman's sister stated that Mr. John A. D——, of San Francisco, aged twenty-seven, had suffered more or less for three years from some lung affection. That a few months before he had experienced an acute attack which confined him to bed for many days. Subsequently his physician had ordered him to Indio, where he arrived two weeks prior to my visit. Mr. D—— had apparently improved, and on March 15th was unusually bright and cheerful. He ate a hearty dinner, but in a couple of hours felt some nausea, soon followed by vomiting. During the afternoon he complained of headache. After taking some light refreshment he retired to bed about 6 P.M., still complaining of headache and languor. About 9 P.M. the sister, who occupied an adjoining room, heard moans, and upon running to her brother's bed found him unconscious. Miss D—— spoke of his cough, expectoration, loss of weight, fever, occasional night-sweats, etc., but could not give exact information regarding any of his symptoms. Evidently it was a case of tuberculosis. I found him lying on the right side, the right arm and hand were cold, perhaps from interference with the circulation. He would lie quietly, as if asleep, for about an hour, or until disturbed. Then for some twenty minutes became restless, tossing his left arm, flexing and extending the lower extremities, moaning, etc. He could swallow liquid placed on his tongue. The pupils were widely dilated. Respiration, 48. Pulse ranged from 80, at 2 A.M., to 140 just before death about 7 A.M. Temperature slightly above normal. The symptoms of this case are necessarily meagre, as Mr. D—— never regained consciousness; but they are sufficient to determine the diagnosis.

I have no doubt that many slight degrees of tubercular deposit in the brain remain latent—so far as symptoms are concerned—and that many other cases exhibit so few indications that we overlook their existence. Perhaps the diagnosis is unimportant—so little can be done for relief. Nevertheless, it is interesting to reflect upon the ubiquity of tubercle.

HYSTERICAL AMBLYOPIA AND AMAUROSIS. REPORT OF FIVE CASES TREATED BY HYPNOTISM.[1]

By J. ARTHUR BOOTH, M.D.,

CONSULTING NEUROLOGIST TO THE FRENCH HOSPITAL, NEW YORK CITY.

We may define hysteria to consist of such a condition of the general nervous system, original or acquired, as renders it capable of simulating most local diseases; of complicating them in their progress, and modifying them in their usual phenomena. The number of derangements and diseases which hysteria is capable of simulating is well known; but defective vision is one of the less familiar forms, and so I take the opportunity to direct your attention to this subject; at the same time reporting a few cases, which may prove of some interest.

This special form of functional trouble, not due to alcohol or tobacco, is, by no means, a common one; this is especially true in regard to the cases of amaurosis; those of amblyopia and narrowing of the fields of vision being more frequently met with.

The onset of the disturbance is usually sudden, and generally follows some shock, either mental or physical. In attempting to examine the eye there is a spasmodic contraction of the orbicularis muscle which is increased on exposure to a bright light, at the same time causing a sense of anxiety, profuse lachrymation, and a spasmodic closure of the lid of the eye. The globe itself does not present anything abnormal, except that in a certain number of cases one may find some anæsthesia of the cornea. (This was a marked symptom in one of my cases, Case IV.) The pupils are equal and react readily and normally. The media, lens, vessels, and fundus are normal, so that the local examination does not lead to any knowledge of the pathological nature of the other symptoms which one learns from the patient. Question the patient, and she complains of defective vision, pain either ocular or supra-orbital, and great sensibility to light. There may be absolute loss

[1] Read before the American Neurological Association, Boston, June 5, 1895.

of sight, generally in one eye, or only amblyopia and a reduction of the field of vision to a small area around the fixation point. Besides the above we find the local and general symptoms of hysteria, viz. : a circumscribed pain over the brow, a globular sensation in the throat, excitability and irritability of the nervous system, palpitation of the heart, a tendency to laugh and cry without cause, irregular, painful, or absent menstruation.

The following cases were referred to me by Dr. David Webster, and well illustrate the above objective and subjective symptoms.

Case I. *Amblyopia and Contraction of the Fields of Vision. Vision Restored in Twelve Séances.*—Kate T——, eighteen years of age, was seen for the first time on June 12, 1894, when the following history was obtained : She had always been nervous, but otherwise had had no trouble until the appearance of menstruation, two years ago ; then, during the first year she suffered much pain each month. For the past year menstruation has come on at irregular intervals, and has now been absent for two months. Within the last six months the patient has become very depressed and emotional, and she has also had two convulsive seizures of a hysterical nature. One month ago a brother committed suicide, and it was shortly after this that she first noticed failure of vision ; at times becoming entirely blind ; this latter condition only lasting a few seconds. Examination does not reveal any organic lesion of the nervous system. Any attempt to examine the eyes causes a spasmodic closure of the lids. Both pupils are moderately dilated and react normally. The vision of the right eye is $\frac{20}{15}$, and of the left eye $\frac{20}{40}$. Both fields of vision are very much contracted, as is shown in Fig. 1.

The fundus, media, and vessels are normal, nothing being found to account for the condition present. Two attempts to hypnotize the patient failed, but on the third trial she passed into a deep sleep, and suggestions referable to the conditions present were made. After seven séances, the fields were again measured and a marked improvement was found, the degree being shown in Fig. 2.

The treatment by suggestion was continued until August 15th, when the patient was discharged with perfectly normal fields and vision fully restored.

Case II. *Amblyopia. Contraction of the Visual Fields. Improvement after Six Séances.* — March 29, 1895. Charles T——, aged twenty-eight, single ; clerk. General health good up to eighteen months ago ; then after some business troubles and excesses, he became depressed, nervous, and could not sleep. Six months ago he noticed that he was having periods of temporary blindness, these only lasting for a second or two. Three months later his vision became blurred, and this condition has remained up to the present time. He has never had any diplopia. Within the last month there has been more or less frontal and occipital headache, and lately he has become very emotional. Sometimes he gets confused and cannot remember dates, otherwise his memory is good. The urine has been examined several times and always found to be normal. At one time he had herpes preputialis, and being told that it was due to a syphilitic infection, thought all his symptoms were caused by this disease.

Examination.—Stands well with eyes closed. Knee-jerks high but equal. Grasp of hands as shown by the dynamometer : R. 44–40 ; L. 40–39. Tongue straight ; speech normal. Pupils equal, of medium size, and active. The ocular muscles thoroughly tested with prisms, do not show any degree of paresis. The optic nerves and retinal vessels appear perfectly normal.

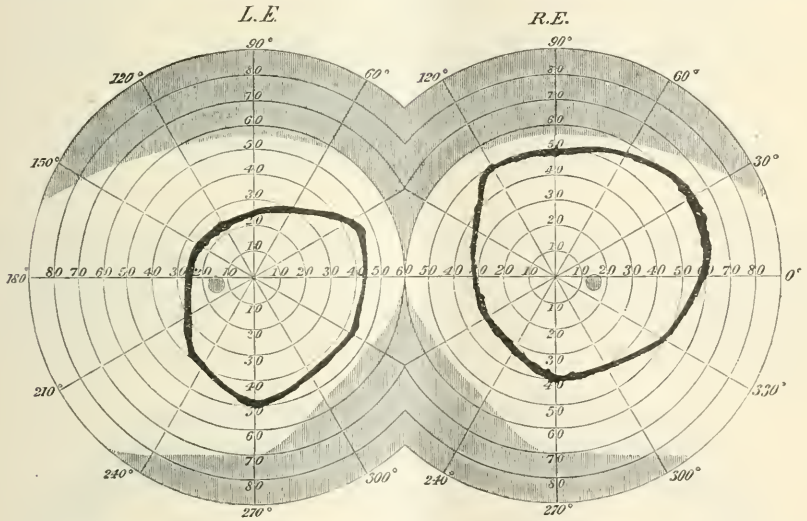

Fig. 1.

Both visual fields are very much contracted. (See Fig. 3.)

There is no loss of color perception. The left side, including the cornea, is slightly anæsthetic, and he now states that he occasionally has a temporary feeling of weakness in the leg and arm of this side. Examination does not reveal the slightest loss of power : all the muscles are firm and react normally to both the faradic and galvanic currents. He was hypnotized without any difficulty, and the proper suggestions were then made. This method of treatment was continued for two weeks, resulting in a complete disappearance of many of the symptoms complained of. The visual fields were again measured, and though some improvement was shown, still there remained a certain amount of contraction. (Fig. 4.)

On April 12th he stated he had been having more or less pain in his abdomen for several days, and that this morning he had passed some white objects at stool. Upon examining these, they were found to be a number of the links of tænia solium. A mixture of castor-oil and felix mas was ordered, with directions as to diet, etc.; which resulted in the passing of two worms, many yards in length, including the heads. Three days later his eye symptoms had all disappeared, the visual fields

were entirely normal, and have remained so up to the present time.

Case III. *Monocular Blindness. Cure in Five Séances.*— Fannie T——, aged thirty-eight, married. Seen November 23, 1892. She was perfectly well until one month ago, about which time she became depressed; could not attend to her household duties and had a number of crying spells. Three weeks later pain appeared in the left eye, accompanied by some blurring of vision, which gradually increased, and now for the past three days there has been complete blindness in this eye. No vomiting, diplopia, or vertigo. There is no history of rheumatism, malaria, or any serious illness, having always enjoyed good health up to the time of the present trouble. She has three healthy children and has had no miscarriages. Careful inquiry does not reveal any history of syphilitic infection. Bowels and menses are regular.

Examination.—There is a complete loss of vision in the left eye: she fails to recognize any object held before it, the right eye being covered. Vision in the right eye normal. Pupils normal in size and active: no ocular paresis. On exposing the eyes to a bright light there is a certain amount of photophobia. The ophthalmoscope shows nothing abnormal either in media, disk, or vessels. With the exception of a slight amount of anæsthesia of the cornea, there were no other sensory changes. The patient was easily hypnotized, and the necessary suggestions having been made, she was awakened after sleeping ten minutes. The right eye was then covered and the left again tested. Vision was about the same, but she volunteered the statement that there was less blur, and the pain had disappeared.

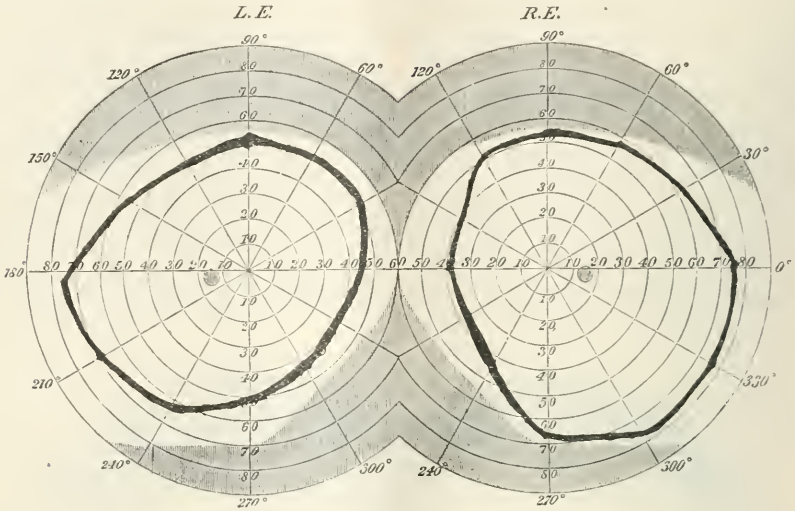

Fig. 2.

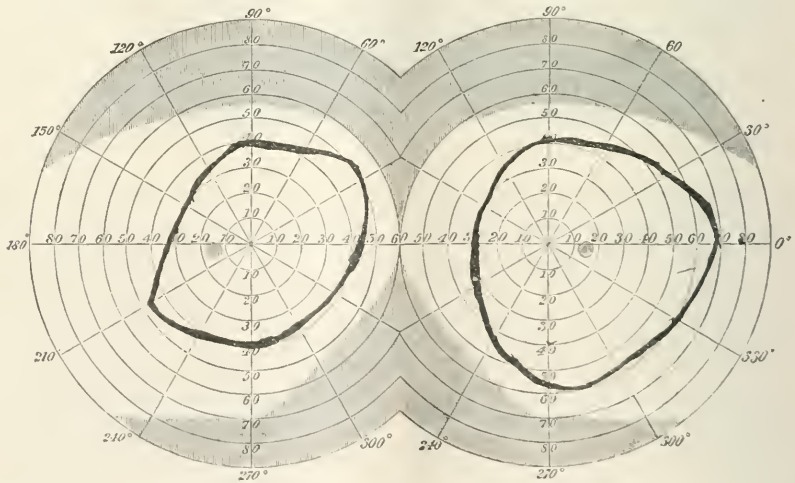

Fig. 3.

November 25th.—No change; condition the same. Vision again tested as before and with the same results. She complains of a good deal of pain in the left eye and face. I hypnotize her and suggest that she will have no more pain; that the rest will do her good and that she will now see. In fifteen minutes she sits up on the couch, and placing one hand over the right eye,

recognizes a clock on the wall twelve feet distant, although she is unable to distinguish the hands or tell the time. A bunch of keys, a knife, and a silver half-dollar are named correctly at four feet. The pain is entirely gone.

December 7th.—Patient reports that she is now able to see much better, also that the pain has been absent since the last séance. She sees well at ten feet, but beyond this everything looks blurred. Séance repeated.

December 9th.—Has been perfectly well: no pain. Vision entirely restored.

Case IV. *Monocular Blindness. Cure in Nine Séances.*—On September 12, 1894, the patient was referred to me by Dr. Webster with the following note: "I see no sufficient ophthalmoscopic reason for the loss of all but perception of light of this young woman's left eye. If you can find no lesion of the brain to cause the blindness perhaps you can restore the sight by hypnotism as you did before."

Mary C——, aged eighteen, married. The patient is an Armenian and cannot speak a word of English, but her physician is present and acting as interpreter, the following history is obtained: Has been married five years: two children and no miscarriages; is now nursing an infant eight months old. Was fairly well up to the past month; during this time she has become depressed, emotional, and has often complained of a lump rising in the throat. A few days ago she had some headpain, and with its appearance she noticed failure of vision in the left eye, and now the patient cannot distinguish any object at any distance far or near, but she can make out the difference between light and darkness. She is poorly nourished and anæmic. Mucous membrane of lips, gums, and conjunctivæ pale. Both pupils moderately dilated, the left not reacting as actively as the right. Fundus entirely normal. Failing to find any evidence of organic trouble, the diagnosis of a functional amaurosis was made and I decided to try suggestion for its relief. The patient not being able to understand English, I was not successful in the first attempt to hypnotize her; but through the aid of Dr. Aterian I learned the proper Armenian words necessary for the purpose and was successful at the third séance in obtaining a deep hypnotic sleep. Complete recovery took place in nine séances.

Case V. *Monocular Blindness. Unimproved.*—This patient had been under the care of Drs. Boynton and Palmer at the Ophthalmic Hospital, and was finally referred to Dr. Webster, through whose kindness I saw the case on February 4, 1895. Although there does not seem to be any doubt in my mind as to the trouble being a functional one, all methods of treatment have proved ineffectual. The following is the history:

Agnes L——, fourteen years of age; single. She was perfectly well up to one year and a half ago: about this time she fell on the ice, striking the back of her head. She was much frightened and jarred, but did not vomit or lose consciousness. Menses appeared for the first time shortly after this, but have never been regular, two months having now elapsed since the last period. Two months after the accident above referred to, the patient commenced to have headache, chiefly frontal, but sometimes in occiput and back of neck. On May 5, 1894, she came under the care of Dr. Boynton, at the Ophthalmic Hospital, for dimness of vision. Examination revealed almost total loss of vision in the right eye, without any change in the fundus, vessels, and disk; all being found normal. While in the hospital she had two epileptoid attacks, hysterical in character, and she also had frequent crying spells.

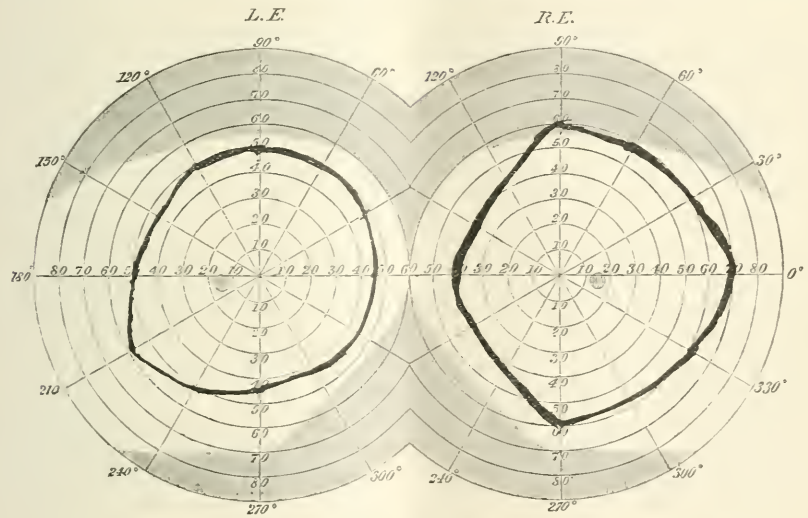

Fig. 4.

Thorough treatment with strychnia, glonoin, iron, and the valerianates caused no improvement.

Examination.—There is a complete loss of vision in the right eye. Left eye vision is $\frac{15}{200}$, brought up to normal with proper glass. Field much contracted in all directions. In a moderate light, both pupils dilated, the right being a little the larger. Reflex through the right retina not as good as through the left. When one illuminates the left retina, the right pupil does not remain contracted as long. With direct illumination the reaction is about the same. There is a marked loss of sensation of the cornea of the right eye, but no anæsthesia of face, body, or extremities. The patient recognizes colors readily. The knee-jerks are exaggerated but equal. The question of simulation was considered, but repeated tests by prisms and other means gave negative results. Treatment by means of drugs having failed to change the conditions present, hypnotism and metalo-therapy were tried, but both failed to influence the patient in any way.

Prognosis and Diagnosis.—From the facts brought out in the above histories, we see that an amblyopia, or amaurosis from hysteria, may be slight in form and transitory in duration, or very severe; sometimes tardy in its progress and prolonged in its existence. If the

condition should persist for any length of time and an alteration of nutrition or any morbid formative process be set up by the prolonged functional disturbance, then it is probable that finally the condition would change into an amaurosis from inflammation and congestion. This latter condition, I now believe, is taking place in Case V., which illustrates well this type of the disease.

The diagnosis is based on two points, viz. : the absence of any demonstrable changes in the eye, and the lack of that agreement between the individual symptoms constituting the disturbance of vision which under other circumstances they would exhibit. Persons whose visual fields are unusually contracted still move with perfect security, without stumbling, in a space which is not well known to them. The only difficulty in diagnosis exists in those cases where a line must be drawn between true simulation and a hysterical blindness, that is, one having an actual existence in the imagination. It is not that they will not, but they cannot will. The retina receives the impression, but through some fault of the higher cortical centres, perhaps by inhibition, the patient remains unconscious of it.

Treatment.—Besides the measures usually recommended in the treatment of these disorders—the internal administration of strychnia, iron, etc.—I wish to urge the trial of hypnotism, and I do not do this from any optimistic point of view.

A great many of us are prone to look upon this entire subject as either belonging to the domain of quackery, or believing that it requires some special power hesitate to take advantage of this method of treatment. The time has now passed for any such argument, and any physician who would take the trouble to study the subject would obtain satisfactory results in a certain number of cases. The manner of procedure in producing hypnosis is given in detail in current literature, so that it does not seem necessary to dwell upon this part of the subject here, except to state that the fixation method is the one generally employed.

From the results obtained in the cases just submitted, the following conclusions may be drawn, viz. : 1. We possess in suggestive therapeutics an important aid in the treatment of certain morbid conditions, but just how valuable this may be, cannot be estimated until it is more generally used and the results reported. 2. The results of this method of treatment are sufficient to stimulate the profession to further use of it. 3. Instead of waiting and trying other methods first, thus allowing the disease to exist for a certain time, I would recommend the trial by hypnotism in the first place. Two of the cases already reported had been treated by other measures for some time without success. 4. The use of hypnotism by the intelligent physician, in the cure of certain morbid conditions, does not produce any bad effects, notwithstanding reports to the contrary.

Gonorrhœa : When Cured?—A patient who has had gonorrhœa and is about to marry asks his physician whether he is completely freed from his disease and without danger of contaminating his wife. In such cases the writer instructs his patient to drink a quart and a half of beer, after which he injects into the patient's urethra a two per cent. solution of sublimate. If he is actually cured, no reaction follows ; if the contrary is true, a discharge will be set up which sometimes does not appear for forty-eight hours. — Dr. Kraft, of Utrecht.

Artificial Feeding of Infants.—I do not advise using milk diluted with plain water for young babies under four months old. The simplest and most commonly used diluent is barley-water, which is almost entirely innutritious, its action being purely mechanical in breaking up the casein.—Griffith.

INTRA- OR EXTRA-PERITONEAL TREATMENT OF THE PEDICLE, OR TOTAL HYSTERECTOMY.

By MARY A. DIXON JONES, M.D.,

Brooklyn, N. Y.

In 1886 I saw Austria's great surgeon, Billroth, treat the pedicle of a uterine myoma intra-peritoneally. More than once did Billroth, with his quick and graceful step, lead me around the wards of his hospital to see this and other patients. To me it was exceedingly interesting to see the kindly and almost childlike enthusiasm of his great mind, then in all its manly vigor. Operating, doing much of surgery, only makes the good man more loving, more kind, and more tender. The patient from whom he removed the uterine myoma and treated the pedicle intra-peritoneally did well.

In Berlin I saw Schroeder treat the pedicle of a uterine myoma intra-peritoneally. Again and again I stood in the operating-room of this excellent surgeon, and was always given by him the most eligible position. This great man also invited me to accompany him through the wards of his hospital. The pedicles of all cases of uterine myoma he treated intra-peritoneally. It seemed a beautiful procedure, except that I occasionally would like to see how the pedicle was doing.

In London I saw Granville Bantock remove a uterine myoma, and he treated the pedicle extra-peritoneally. That first day—the first operation at which I was present—there was a crowd to see the great operator. I imagined I would scarcely be able to get a glimpse. I stood far on the outside. Bantock came in his quiet, amiable manner ; he looked at his instruments, saw that all was right, then with a kindly glance of his mild, penetrating eye, and almost a suppressed smile, he, with inimitable grace, said : "The shortest to the front." This gave me a place opposite and near to the first assistant. The pedicle had attached to it a number of little fibroid tumors. It was a difficult case to manage. Bantock concluded to leave some attached. Dr. Dornan, the first assistant, subsequently gave me a picture of this mass of tumors. I was privileged to see Bantock in many operations, he always stood at a distance from the table, nowhere and at no time touching it, but with a firm position he directed the whole strength of his body to the thoughtful manipulations of his hands.

In the Woman's Hospital of New York I saw Dr. Charles C. Lee remove a large fibroid tumor, extra-peritoneal treatment of the pedicle. Dr. Lee also most kindly gave me opportunities of seeing the condition of the pedicle from time to time. The patient did well. I saw Dr. Wylie remove a large fibroid tumor and treat the pedicle extra-peritoneally. The operation was beautifully performed and the patient made an excellent recovery.

On August 15, 1887, a poor colored woman came to see me at the dispensary, complaining of much pain and distress on each side of the pelvis, and in the region of the bladder and rectum. She said she had had a constant hemorrhage, varying in quantity, since the third of the preceding May. I found the uterus enlarged to the size of the seventh month by an intermural myoma, the lower part being wedged tightly down in a small contracted pelvis. Some weeks after, this woman called again at the dispensary, she was still bleeding, sometimes profusely, and was growing weaker and weaker. We feared her life might be in danger, so we admitted her into the Woman's Hospital of Brooklyn, then located at 725 Greene Avenue. She was in an extremely feeble condition, that evening having repeated chills. After a hot bath and fresh clothing she was placed in bed, with a jug of hot water to her thin, bloodless feet. Day after day she had the most careful nursing, the best nourishment, and constant medical attendance. In some respects she seemed to improve,

notwithstanding the bleeding and other serious symptoms continued. We decided to remove the tumor, which, after the usual preparations, and with the assistance of Dr. C. N. D. Jones, I did, on November 15, 1887. The omentum was generally adherent, and especially bound firmly in the region of the uterine appendages. After liberating it, and tying the broad ligaments, with one hand under the tumor, and the other with Tait's screw, the mass was lifted from the abdominal cavity. There were especially grave difficulties in securing the uterine pedicle, it was very short; many fibroids were shelled out, finally it was transfixed with pins and placed in the lower angle of the abdominal incision. The womb was dressed two or three times each day, and the patient was apparently doing well; still for weeks this woman lay on her back, as if chained by some great weight. Day after day, as I rode around to see other patients, my thoughts continually recurred to this poor colored woman in that bed in the hospital. I knew that the continued dragging of that pedicle was to her a continued shock. I knew that that pedicle was placing her in constant danger; and of what possible utility would it be; what advantage was there in retaining that dense piece of fibrous tissue, that piece of cervix which in most instances is diseased? Why not remove it? To me the clear sunlight of heaven shone into that poor woman's abdomen. I could see that useless piece of hard cervix festering and disturbing adjoining structures, and so out of place amid the soft peritoneal tissues. Continually I could see more and more the beauties of removing it. Over and over again, I mentally went over the operation of removing the cervix, saw that it was feasible and safe, and would be so much better for the operation and for the patient! Why was it ever thought necessary to retain it?

In both methods of operation, extra-peritoneal or intra-peritoneal, it is the stump that makes the difficulty; it is the source of most of the danger, and statistical history shows that the great mortality of this operation is due almost entirely to unfavorable conditions originating in, or generated around, the stump. Emmet reports a case. "The stump was almost all cut away, leaving only enough of the cervical tissues to hold the ligatures from slipping off, and it was so covered as to be placed outside of the peritoneal cavity; yet on the fourteenth day the patient died from rupture of an abscess." This distinguished operator says further: "I have removed the whole or portions of the uterus in five instances, and, notwithstanding the greatest care to insure a favorable result, all the patients died, sooner or later, from blood-poisoning generated about the stump." Shall we say it is a safe method when it is so frequently fatal in the hands of our best operators? It is not the operation, or the method of operation, but it is the danger which is inherent in the stump, or in this method of procedure.

On November 23, 1887, when I was privileged to present this tumor that I had removed on November 15th, before the New York Pathological Society, I stated that I believed a better and more natural procedure would have been, after opening the abdominal walls—being assured of the condition of affairs, and liberating any adhesions that might exist—then to have severed the vaginal connections, as in colpo-hysterectomy, and so remove the entire uterus. Or, if the body of the tumor or uterus were removed through abdominal incision, then to remove the uterine stump per vaginam, and, after "la toilette du péritoine," close the abdominal walls and leave the vaginal opening as the best and most natural mode of effecting drainage. I also gave the following reasons for favoring this procedure: 1, It would shorten the operation; 2, would be less shock to the patient; 3, would lessen the dangers of the operation; 4, the patient would make a rapid recovery.

I carried this method out February 16, 1888, for a tumor altogether weighing seventeen pounds. The patient came to my office January 17, 1888. Forty years of age, twice married and no children. A uterine myoma extended from the cervix to within an inch of the ensiform cartilage, and was larger than the uterus at term. Her emaciated body seemed only a framework to support the growth; she wished to have it removed. I told her of the dangers of the operation, yet I believed it was the only way to give her any relief.

At the next visit she informed me that she had seen a physician whom she had previously consulted, and he had told her that if she had the operation she would die on the table. She replied to him that she had rather die than remain as she was. I again assented to, and emphasized the dangers of the operation. She still said she wished to have the tumor removed. She was admitted into the Woman's Hospital of Brooklyn, February 5th. Operation performed February 16th. As she lay on the operating-table under ether, the body seemed a mere skeleton; the monstrously large and nodulated tumor filled the whole abdominal cavity, extending up to and under the ribs. A small exploratory incision was made first midway between the umbilicus and down to the pubes. I passed my hand in and around to free adhesions, then by the help of Tait's screw, with the left hand beneath, the mass was lifted out of the abdominal cavity. The right tube was greatly enlarged, presented the appearance of a coiled-up and adherent mass of intestine; the left tube was also adherent, its fimbriated extremity closed, and the tube filled with pus. The tumor was removed. "The pedicle thus secured consisted of a mass of tumors, one of them three inches in diameter, all closely packed, reaching to the cervix. I knew that to make a pedicle of the mass would not only endanger the patient's life, but render the operation unfinished and imperfect, so I decided at once to proceed as in vaginal hysterectomy for the removal of this portion." I separated the vaginal attachments—the size of the mass rendered it necessary to remove through the abdominal incision. Drainage was secured both through the vagina and abdominal womb. By thus removing the entire uterus we not only got clear of the stump, but of the great mass of loose tissue which surrounded it and which, if it had remained, would doubtless have produced the most serious consequences; and which is probably an explanation of why the report has so frequently to be made of death on the ninth, twelfth, or fourteenth day from abscess near the stump. I do not see how in this case, with every precaution, the formation of an abscess could have been prevented in so much loose issue.

It was marvellous to see how much more rapid was the convalescence of the patient than it would have been had not the stump been removed. Keith says: "The average time of convalescence in the extra-peritoneal cases was forty-one days; of the intra-peritoneal method, three weeks." This patient was practically well on the twelfth or fourteenth day, had an excellent appetite, and had gained in flesh and strength. No such results could possibly have been secured if the stump had been left.

If the pedicle or cervix is removed, it should preferably be treated extra-peritoneally, though one of our first authorities, Dr. T. A. Emmet,[1] said: "If myotomy was to have a future, it would have to be done by covering the stump with the peritoneum and dropping it into the peritoneal cavity." Professor T. G. Thomas[2] said: "He had removed the uterus from seventeen patients; nine of them had recovered and the remainder had died. A large number had been treated by the clamp, and they had done remarkably well. A smaller number had been treated by simply returning the pedicle, and they had done badly." Dirner, of Buda-Pesth, Hungary, says the extra-peritoneal method prevents hemorrhage and sepsis more completely than the

[1] American Journal of Obstetrics, January 5, 1885, p. 85.
[2] Ibid., January, 1887.

other method. Greig Smith[1] says: "The dangers of the intra-peritoneal treatment are nearly twice as great as the extra-peritoneal." As I said in an article published in the *New York Medical Journal*, August 25, 1888: "But, even when the stump is treated extra-peritoneally, there are many dangers, and may be much trouble, as of an operation performed September, 1887, by one of the most distinguished living gynecological surgeons and at a centre of gynecological science, the record is death on the seventh day 'from pus cavity on one side of the pedicle.' We may seek to produce the best conditions, but there are still foul septic discharges, and, if the patient recovers, it is only the question of escaping the many dangerous possibilities. At best the stump is a hard, fibrous mass, extending from the vaginal to the abdominal walls, and pulling upon both. In this case I have reported the traction upon the abdominal walls was so great that it made a considerable sink or depression in the surface, and caused such pressure from the pins that, notwithstanding every care and all possible disinfection, keeping constantly fresh gauze under the pins, yet beneath them the skin sloughed, and with all this there were the threatening dangers of sepsis, abscess, etc., from the decaying stump. Is a course of procedure the wisest that is necessarily accompanied by, or may encounter, such grave conditions? What is the good of preserving the stump intra-peritoneally or extra-peritoneally? It is only the remnant or remains of a sickly womb, and can be of no service and may do much damage—how much, who can tell?—not only at the time of the operation, but in the subsequent history of the patient. One case is reported in which 'within a year cancer developed in the remains of the cervix and proved fatal.'"

Dr. Joseph Price's magnificent results have done much to favor the extra-peritoneal method, still surgeons have long recognized the dangers of the stump, whether much or little is left, or whether treated intra- or extra-peritoneally. Professor W. M. Polk, at the meeting of the New York Obstetrical Society, June 15, 1889, said:[2] "Leaving a large suppurating, or rather gangrenous, stump is a surgical fault threatening the life of the patient, and improved means should be devised whereby it can be got rid of." He adds: "I should like to have the question under discussion broadened so as to take in the views of the members upon the propriety of total extirpation of the uterus, after ligation of the uterine artery. I believe it is time to look about for means of getting rid of the slowly sloughing stump, which is constantly a source of danger in addition to what pertains to ordinary laparotomies."

Dr. E. W. Cushing, of Boston, on March 28, 1895, read before the Gynecological Section of the New York Academy of Medicine a paper on "Histerectomy and Total Extirpation of the Uterus by Abdominal Section." He gave the evolution of hysterectomy in this country, quoting from the *New York Medical Journal* of August 25, 1888, that the first case of total hysterectomy in this country for uterine myoma was performed by Dr. Mary A. Dixon Jones, February 16, 1888. Dr. Cushing referred to the various improvements in this operation, and the excellent work done by Drs. L. A. Stimson, William M. Polk, Joseph Eastman, B. F. Baer, and others. During the discussion Dr. Baldy, of Philadelphia, said he thought "it would be better to leave a small portion of the cervix." Dr. F. Krug, in a short address, favored the idea that all the cervix should be removed. Dr. Krug had on a previous occasion said that "total hysterectomy is an ideal operation." At a meeting of the New York Obstetrical Society, November 5, 1889, when Dr. Boldt presented "an interstitial uterine fibroid," removed by my method of total extirpation of the uterus, Dr. Dudley inquired: "What advantage is there in removing all the cervix over that form of hysterectomy which leaves part of the cervix as a stump?" Dr. Boldt well replied, "By leaving a portion of the stump, the patient is exposed somewhat to sepsis, which can be avoided by complete hysterectomy."

As to Goffe's method, I said in a paper published in the MEDICAL RECORD, September 6, 1890: "Goffe's method, as reported by the *New York Obstetrical Journal*, is, as he describes it, 'taking out the whole of the uterus except a bit of the cervix, covering this over with peritoneum.' But in all his cases, as he reports them, the temperature went up the fourth or fifth day, which, says Dr. Goffe, 'means suppuration under the flap, with danger of the pus bursting into the peritoneal cavity;' so in each case he dilated the cervix, drained, and irrigated. Of one he said, 'A gentle amount of pressure caused the exit of about half an ounce of pus and broken-down tissue.' The same procedures are used by Dr. A. P. Dudley. 'He dissects out the uterus to about three-fourths of an inch of the cervix.' The third day there is the same rise of temperature, the same process of dilating for discharge of pus. Thus, invariably, a certain amount of suppuration seems to accompany this method, so, with 'a bit of the cervix left,' there cannot be, as Dr. Goffe expresses it, 'all the elements of safety.'"

Dr. E. W. Cushing dwelt at length upon, and especially commended, Dr. L. A. Stimson's method of first tying the uterine artery: which is indeed an excellent way of controlling hemorrhage; but Dr. Polk, at a meeting of the New York Obstetrical Society, February 18, 1890, said that[1] "the searching for the uterine artery down by the side of the uterus, and ligating and enucleating separately, was according to the plan of Dr. Stimson, but as a matter of fact it was unnecessary, for one could ligate *en masse* without any difficulty." He said, further, "Ligating *en masse* shortens the operation." Dr. Bantock reported in the *British Gynecological Journal* for 1890, page 75, "the very first case in which he removed a fibroid tumor from the uterus he secured both the ovarian and uterine arteries separately, and then put a serre-nœud around the body of the uterus, and it was extraordinary how much bleeding he got."

At the same meeting Dr. Polk incidentally remarked: "The operation introduced into this country by Dr. L. A. Stimson, of removing the entire uterus including the cervix." Is not this a mistake? Dr. Stimson says his first two cases were reported to the New York Surgical Society, January 9, 1889, published in the *New York Medical Journal* March 9, 1889. My first case was reported to the New York Pathological Society February 22, 1888, and published in the *New York Medical Journal* August 25, and September 1, 1888.

Dr. Mendes De Leon, of Amsterdam, wrote me October 20, 1888: "Only yesterday I returned from a trip to Berlin. Martin told me he had performed four hysterectomies, with vaginal extirpation of the pedicle. As soon as he will reach the series of ten he intends to publish it. Is this method of tying the pedicle yours or his? I am very anxious to know more about this question. Perhaps you may find time to let me know one of these days."

Professor A. Martin, of Berlin, was in this country only two months before I presented the subject to the Pathological Society. In several of his addresses while here he spoke of the treatment of the pedicle, strongly favoring the intra-peritoneal method; so far as I know he did not mention the vaginal extirpation of the stump, nor did anyone else previous to my publication in November, 1887.

Dr. Joseph Eastman said in the *Cincinnati Lancet-Clinic*, December 8, 1894: "Dr. Mary Dixon Jones, of New York, was the first in America to take out the entire cervix." This, so far as I know, is true; at least I had never heard of its being done, nor do I consider

[1] Opus, second edition, 1888.

American Journal of Obstetrics, 1890, p. 533.

the method in any way an imitation of Freund's operation. It has different uses and a different object. Further, I think a cancerous cervix should be removed only through the vagina — should never be taken through the peritoneal cavity. One reason why I, in my article on "Colo-hysterectomy for Malignant Disease,"[1] so emphasized delivering the uterus by anterior version, was that by posterior version, the usual method, the diseased cervix was so often, unintentionally, thrown into the peritoneal cavity.

While it is admitted that I was the first one in America to perform total hysterectomy for uterine myoma, still I have now to record that I was not the first person who did this operation. I have found out, only a short time since, through the kindness of Dr. H. G. Garrigues, that there were four cases of "Total Extirpation of the Uterus for Fibroid," performed by Bardenheuer, of Cologne, Germany, and these cases were reported as an appendix to a book entitled "Drainierung der Peritoneal Höhle," Stuttgart, 1881. Perhaps if we search the records further we may possibly find the same operation was done by an ancient Egyptian physician for some poor suffering woman.

AN OPERATIVE PROCEDURE FOR SPINA BIFIDA.

By H. HOWITT, M.D.,

GUELPH, ONT.

ALTHOUGH the Ontario Medical Association has a large membership-roll, I doubt if it has a single member who has seen an adult with an undoubted and well-marked spina bifida. On the other hand, according to the excellent authority of Holmes, the congenital malformation probably occurs more frequently than any other except hare-lip. The inference to be deduced requires no words of explanation from me.

In the early years of my practice I attended a lady in confinement who gave birth to a vigorous and apparently well-formed male child. But when the little one was having his first introduction to the delights of soap and water, the nurse noticed an enlargement on the back. An examination revealed a smooth, globular, cystic tumor, about the size of a small egg, in the middle of the lumbar region, immediately under the skin. Its nature was known to me, but at the time, in regard to its serious import my knowledge was wanting. Partly from want of information, and partly to allay the anxiety of the mother, it was my misfortune to make light of the trouble, and even to hold out hopes for a cure. On reaching home and consulting my books it was plain to me my prognosis was somewhat astray. However, something had to be done. The method of treatment strongly advocated by Dr. Morton was rejected, because to my way of viewing the subject no one could be sure that the irritation set up by the injection would limit its action to the sac. For want of a better plan that of applying pressure was adopted. As time passed, in spite of my best efforts the tumor continued to grow in size. The family became alarmed and changed their medical adviser. This was done again and again, until one more heroic than those who had preceded him promised a cure by an operation. The doctor had evidently Morton's operation in view, for he decided to tap the sac and inject a preparation containing tincture of iodine. Possibly from want of practical skill and an understanding of the details, the operation was not completed. For, on passing the trocar, considerable fluid was permitted to escape, and before the injection was used the child took a convulsion. He never rallied, in a few hours a coffin was purchased, and presently a tiny grave in the cemetery forever hid from the world all the material evidence of the mistakes that had been made in our sincere though ineffectual efforts to save the little one.

The case made considerable impression on my mind at the time; besides, being stung by the knowledge of the fact that my erroneous prognosis had resulted in the loss of the family in my then limited practice, I determined to study the subject as carefully as my ability and means at command would permit.

The following paragraphs contain, in reference to treatment, the gist of the conclusions arrived at by me:

1. That one of the most important functions of the cerebro-spinal fluid is to regulate the tension of the great nerve-centres, and hence the blood-supply to them. For illustration grasp with your hand a spina bifida, and what is the result? At first the child becomes restless and cries, then if you increase the pressure, a convulsion, still more, coma and death. On the other hand, withdraw the fluid from the sac (provided there is free communication between it and the subarachnoid space) and you have equally alarming results.

2. The spinal membranes, and consequently the walls of the spina bifida, resemble the peritoneum in being apt on irritation to form adhesions. This provision safely allows the communication between the sac and cord to be closed by a suitable ligature, provided sufficient care is taken to prevent septic germs from obtaining admission.

3. Neither the size of the tumor nor the breadth of its skin base has any significance in regard to the character of the communication between the sac and cord. A large sessile spina bifida may have so small and imperfect a communication that the tumor may be drained without materially disturbing the tension of the cord. This fact accounts for occasional cures by tapping, irritating injections, and other equally unscientific modes of treatment. On the other hand, a small one attached by a pedicle may have such free connection that even to tap it leads to disastrous results. It is quite natural to suppose that the delicate cyst of a spinal hernia, when it impinges against the skin, may meet sufficient resistance to cause it to extend laterally. This explains why a large one may have an exceedingly small pedicle.

4. That we are not to follow the advice given in our text-books, namely, to estimate the amount of bone deficiency and chances of nerve-tissue being implicated in the protrusion by the size and outline of the tumor, but to do so by the general condition of the infant, and especially the extent of paralysis in the parts below. All portions of the cord which escape into the sac, and which are attached to and follow its inner wall, are permanently destroyed so far as their natural function is concerned. In other words, we have paralysis in the parts supplied by them, and they may be removed without adding one iota to the paresis.

5. Spina bifida is frequently accompanied by other congenital deformities such as talipes, sphincter paresis, hydrocephalus, and paraplegia. The last named is always, and hydrocephalus generally, incompatible with viability. Hence quite a number of the cases are from the first beyond the possibility of cure.

6. That no operation will successfully stand repeated trials by different operators, unless in its performance a provision is made to prevent disturbance of the tension of cord.

7. The higher the tumor is placed on the spine, the more delicate are the walls of its sac, the greater the irritation to it by the movements of the child, and the more difficult it is, other things being equal, to treat.

Having come to the above conclusions the treatment indicated to me appeared quite clear and devoid of any serious difficulty; but nearly two years passed before I had an opportunity to give it a practical test.

The operation that I advise is very simple and is easily performed. The only instruments absolutely necessary besides sutures and an aseptic silk ligature are a needle and scissors, one blade of which is probe-

[1] American Journal of Obstetrics, November, 1893.

pointed. But it is better to have also a scalpel and two hæmostatic forceps. Nevertheless, it is very essential that the operation should be done scrupulously in accordance with every detail of modern clean surgery; for if any form of septic infection reaches the delicate structures within the spinal column there is only one result—failure.

When normal skin covers the whole of the tumor, we first mentally or otherwise map the outlines of skin-flaps necessary to close the wound left by removal of it. Then having carefully perforated the skin, the probe-pointed blade of scissors is introduced between it and the membranes of sac and the skin divided. The flaps are now by fingers or handle of scalpel separated from cyst down to the fascia of back. Then the tumor is by same means parted from its loose attachment to fascia till the pedicle is exposed.

A prepared silk or other suitable aseptic ligature is tied as deeply as possible on the pedicle and all external to it removed. After the oozing has ceased the wound is closed and dressed. The dressing I prefer consists of a pad of iodoform or bichloride gauze next the wound, then absorbent cotton, and over these a piece of oiled silk. The margins of the latter are sealed to back with collodion, and thus the urine is prevented from reaching the part. In ordinary cases it is not necessary to change the dressing until the wound is healed. But when an unusually large spina bifida is removed, the puckers of the irregular flaps and the amount of oozing may demand a provision for drainage during the first day or two.

When part of the tumor has no cutaneous covering, the line of primary cut for making flaps should run in the skin at least a quarter of an inch from margin. There is always sufficient to make the flaps.

No matter how smoothly things may proceed after the operation, the child should be kept in its cot and as quiet as possible for two or three weeks, or until all local irritation has entirely passed away. A limited amount of paralysis in the parts below does not by any means contra-indicate the operation; nor does, under similar circumstances, the presence of nerve-tissue in a case with translucent wall. The operation in these cases neither aids nor increases the paresis. It should never be performed on a child who has hydrocephalus, paraplegia, or other necessarily fatal ailment.

When we exclude the one mentioned in the beginning of this paper, in my own practice, only two cases suitable for operative interference have occurred; both of them in 1885. I have had, however, several reports of cases sent to me by my medical friends who previously obtained the details of the operation. Unfortunately on account of want of care on my part one or two of them may have been lost.

Below are short notes of the cases in the order in which they took place:

Case I.—B. A——, born April 18, 1885. At birth a plump, vigorous, and in other respects well-developed male infant. Tumor situated in lumbar region and covered with normal skin. At first its size was not larger than a pigeon's egg. Slight pressure on it caused child to become restless and cry. By end of week tumor had more than doubled its original size. I advised operation, but at first parents objected. In three weeks the size increased to that of a large orange. By this time the infant had to be kept lying on its side, and could not bear any form of clothing on part. He now seldom took the breast, lost flesh, and became very fretful.

Operation, May 13th.—It was easily performed. Pedicle where ligature was applied nearly an inch in diameter. The recovery was satisfactory in every respect. To-day there is merely a slight scar over the spine, just below the middle of lumbar region, to indicate the situation where the spina bifida was attached. My patient, who is now over ten years of age, is a strong, active, and intelligent youth.

Case II.—C. M——, male, aged six, was examined by me at my office in August, 1885. I found the boy, considering age, well nourished. On the lower part of the lumbar region he had a tumor fully three-fourths the size of his head. The greatest diameter of it was at the base. Its summit was devoid of skin and semi-transparent. Through this portion could be plainly seen a thin band of nerve-tissue, half an inch wide, and several smaller fibres on each side of it. The nerve-tissue extended from above to the edge of true skin below, where it was hidden from view. He had talipes equinus of right foot, some atrophy of the leg, and considerable vesical sphincter paralysis. The boy made a good recovery. He is to-day an active and intelligent young man. The paresis has neither been improved nor aggravated by the operation.

The next two cases are from the practice of Dr. A. Mackinnon, of Guelph, and are given verbatim from report kindly furnished by him.

Case III.—Mrs. F——'s child, born August 6, 1886. The tumor was very small at birth, and appeared to spring from the level of the third cervical vertebra. Though the head was large the child was in other respects well formed.

October 1st.—The tumor had grown rapidly, being now about the size of a hen's egg. The larger portion of its surface was bluish in color and the skin very thin. Under chloroform the tumor was removed according to the method suggested by Dr. Howitt.

October 15th.—Found the wound perfectly healed, but it was now obvious that the child had hydrocephalus. The size of the head rapidly increased.

November 1st.—The little patient died this morning from convulsions.

Case IV.—G. McM——, aged six. At birth a tumor about an inch in diameter was found attached to the sacral region. It now (June, 1887) measures vertically over the tumor fourteen inches, and transversely twelve inches. It is freely movable and is covered completely by skin of normal appearance. Below, it presents two appendages; one about two and a half inches long and about the same diameter as the vermiform appendix which it resembles somewhat; the other is about an inch in length and looks very like a rudimentary penis, from which occasionally oozes a drop of clear watery fluid. (See figure.) The boy is of good size, bright and intelligent in appearance, and has good muscular development in all his parts. He has always had incontinence of urine, and only a very imperfect control over his bowels. A central vertical line through the tumor would correspond to the median line of the body. It appears to be attached to the lower part of the sacrum.

June 16, 1887.—The same operation as in Case III. was performed. By very careful dissection this huge mass was found to have a pedicle smaller than a lead-pencil. The cleft of the sacrum was very small, but higher than had been supposed prior to the operation.

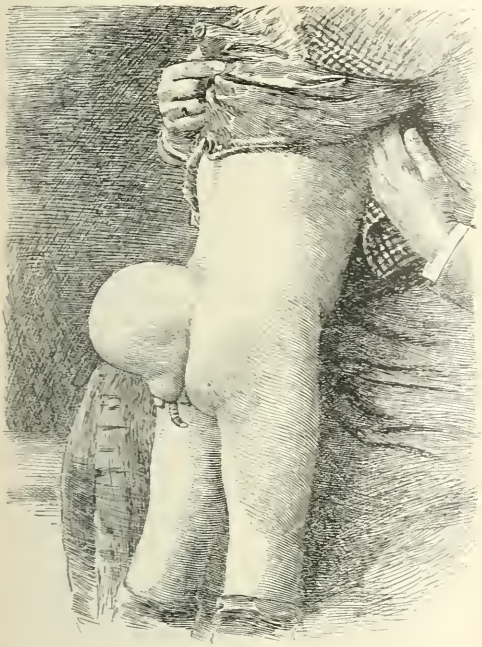
July 5th.—He left the hospital, the operation wound almost healed. He remained perfectly well and went to school the following winter.

March 30, 1888.—Suffered for ten or twelve days with symptoms of meningitis which ended in death, nine months after operation. The doctor has given me a photograph taken before operation of his remarkable case.

The next is from the practice of Dr. William Lovett, of Ayr, and is also given verbatim. The operation was performed by him on May 1, 1890.

Case V.—C——, a healthy boy, six months old. When born a slight tumor about the size of a plum was situated at the level of the lower lumbar vertebræ, which gradually increased until I saw it, when it was the size of a large orange, or perhaps better the shape of a lemon, one-half covered with skin. Having operated three times by Morton's operation without success I wrote to Dr. Howitt for his plan of operation, which to me appeared the most reasonable and scientific. Assisted by

Dr. Burt we proceeded to operate, using antiseptic precautions, by dissecting off as much of the skin as would make a full flap; but as the skin was firmly adherent to the tumor from the irritation produced by lying on it, we wounded it three times. Each time I immediately caught it in my fingers and applied a pair of forceps; having got to the base we separated the pedicle from the surrounding opening in the vertebræ. We then tied it with strong aseptic silk and cut it off, clos-



Spina Bifida. Case IV. of the report.

ing up the flaps and sewing with gut. I then applied a pad of bichloride gauze over the wound, and upon it a large piece of gutta-percha tissue sufficiently large to cover it well, around the under surface of the margin of rubber. I brushed with collodion, which made a firm attachment, air-tight, with the skin so that it was perfectly free from danger of the urine of the child interfering with the operation. I left this for five days; again dressed it. The case continued to heal without a single unfavorable symptom; the opening, which was left, by the undeveloped laminæ has been gradually lessening. I feel satisfied that had it not been for the operation that ere this (seven months later) the child would have been out of existence, whereas we have it perfect in every respect.

Case VI.—(Reported by Dr. Wardlaw, of Galt). Date of operation, September, 1890. Baby S——, aged three days; tumor situated over lower lumbar vertebræ (used chloroform). Washed with bichloride solution (1 to 4,000). Made incision through skin on each side up as far on tumor as possible. Owing to thinness of skin could only get about one and a half inch. Then made incisions around each side, joining side incisions and dissected skin, etc., down to base. Ligated and severed pedicle and returned stump. Stitched up flaps and dressed antiseptically, covered up with satin tissue.

Being so low down, had some difficulty in keeping urine, etc., from wound (nurse not being very careful); but it healed all right, and yesterday I heard that the child was doing nicely, and its back all right.

Case VII.—Report taken from a private letter received from a friend at a distance. It lacks particulars but is extremely candid:

"I followed the instructions given me by you in the case of spina bifida. Had mother and child go to the hospital here. The operation turned out as you stated, except that the pedicle was much larger—would almost admit the tip of my little finger. The sac was as large as a small orange, and its walls extremely thin, and they were ruptured, but a ligature prevented the sac from being emptied. Child rallied and did remarkably well for a week. And now comes the point where I have wanted to kick myself ever since. The child was so well and the mother so anxious to get home that I consented, and that afternoon and evening the child was on exhibition to the neighbors, the delighted mother acting as show-woman. It wound up about midnight with convulsions, and death the next day.

"Examination of the wound after death found it perfectly sweet and its surface adherent. Cause of death, stupidity of surgeon and disobedience of mother."

Four of the patients are alive and well to-day. The last case is the only one, in my opinion, in which death should be attributed to the operation, and even in it under more favorable circumstances the result probably would have been quite different. The procedure, you will admit, has so far proved highly satisfactory.

The more my attention is drawn to the subject, the more I am convinced that spina bifida, in an otherwise healthy child, will, with comparatively little risk, yield to the treatment.

A MARKED CASE OF EXOPHTHALMOS DUE TO INTRA-ORBITAL CYST.

By CHARLES I. PROBEN, M.D.,

NEW YORK.

That exophthalmos of such a marked degree as depicted in the cut should have existed for seven years, and have escaped the scalpel of the eager surgeon, is

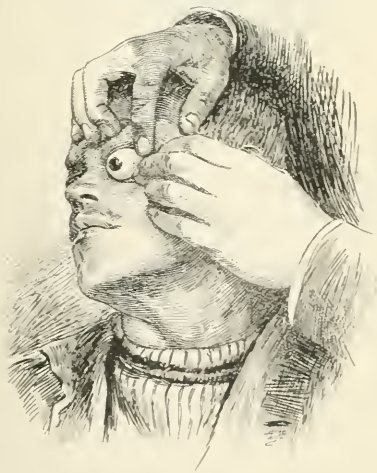


Fig. 1.—Exophthalmos Due to Intra-orbital Cyst.

about as remarkable in this progressive chirurgical decade as the rarity of the lesion itself. The lesion, not being of a painful character, nor in any way interfering with the vocation of the afflicted, relief was simply sought for its cosmetic effect, in order to avoid the conspicuousness of this unique condition. The annoyance the patient was subjected to, owing to the hideous appearance of the deformity, led him to desire

an operation, which would otherwise not have been considered. The hope that this rare condition may be of interest has incited me to record the history, with a few remarks relative to this subject, with the accompanying illustrations, for which I am indebted to Dr. Frederick Roth. The perspective (Fig. 2) shows exceedingly well the hideous appearance produced by the dislocated organ lying far below the horizontal plane of the other eye, which is in its normal situ. The profile view (Fig. 1), in which the lids are retracted, depicts the complete exophthalmos, exposing the entire eyeball. The lids are easily retracted without any pain, and tend to contract behind the dislocated organ. This very marked dislocation was commented upon by different medical men as a rare condition. The patient's history was as follows: A strong, healthy Italian, of vigorous physique, who emigrated from his native land five years ago, aged twenty-six; with a negative family history, the parents being alive and healthy. No history of tuberculosis, syphilis, tumor, or other infirmity elicited. All the patient remembers is that he never had had any of the exanthemata, and that he only suffered from repeated attacks of gastric dyspepsia. A special inquiry and examination fails to reveal any evidences of syphilitic infection. Absence

Fig. 2.

of history pertaining to carcinoma or to any form of local traumatism. General health excellent. The first clew pertaining to the recognition of the exophthalmos dates back seven years, when the attention of the patient and his friends was attracted by a mere protrusion or prominence of the eyeball. The apparent exophthalmos was, no doubt, produced by a neoplasm, which must have existed for a long time prior to its producing the noticeable deformity. From its slow growth and freedom of symptoms we surmise the benign character. The time of its existence can only be conjectured, whether years, or possibly of congenital origin. Taking the slowness of the growth into consideration, during the last seven years, from the time of its apparent inception, we must at least surmise its existence, prior to this period, from five to ten years. Its insidiousness, slow growth, freedom from pain, and the uncertainty of the period of its existence, make the etiological factor very dubious. The deviation of the pathological from the normal condition can readily be perceived by a comparison of the following measurements:

	Oculus Dexter. Centimetres.	Oculus Sinister. Centimetres.
From median line	3·4	4·4
From brow	1·9	3·7
Interciliary space	⅝	1
From inner to outer canthus	3·7	4·4
From cornea to meatus auditorium	7·5	9

From the above we ascertain that there is a marked protrusion of the eyeball of 1½ ctm., with a dislocation downward, 2 ctm., and outward, 1 ctm. The globe, as far as can be ascertained, is normal in size and of normal tension. Absence of pulsation and bruit. Ophthalmoscopic examination negative, visual field and size of pupil normal. Sight, O. D., $\frac{20}{20}$; O. S., $\frac{20}{40}$. Reaction to light and accommodation. Humors clear. Absence of pain, excessive tenderness or congestion of the cornea or sclera. The dislocated organ lies upon the orbital edge of the superior maxillary bone restricted in its movements. When gathered between the fingers after retraction of the eyelids the organ is practically outside of the orbital cavity. The tissues of the eyelids have gradually hypertrophied *pari passu* with the descent of the eyeball, covering it completely. The distance between the eyebrow and the ciliary margin has been much increased, not due to tension but a real hypertrophy. The weight is borne by the lower lid and the sagging produces a semilunar interciliary space instead of a normal elliptical one, making the fissure appear much larger. Puncta lacrymali situated much lower than normal. This leaves the globe not as well protected as it should be. Motion is more or less limited, especially abduction, adduction, and rotation; the upward motion is interfered with by the tumor very perceptibly and is checked at a certain stage. The natural habitat of the globe in the orbital cavity is occupied by a rounded, fairly well-defined, soft, fluctuating mass, partly discerned through the lids, regular in outline, partly movable, and conspicuous by absence of any attachment to neighboring walls or to the eye. Its freedom from tenderness, its peculiar fluctuating feel, its absence of pulsation, or non-attachment to other organs indicates a cystic growth. Neighboring glands are normal. The nares, naso-pharynx, or antrum do not reveal any pathological conditions which may guide us as to its origin. Absence of pressure or reflex symptoms. To recapitulate: we have a cyst occupying the greater part of the orbital cavity, free from adhesions to its walls, the lids, the eyeball, or its nerve, producing by its slow continuous growth a marked protrusion of the eyeball, with an enlargement of the extrinsic tissues and coverings, and what is of most interest is the normal overgrowth of the optic nerve, this revealing no pathological condition at its endings in the retina.

From measurements accurately taken we must assume that an elongation of the optic nerve has taken place of nearly two centimetres. This is both interesting and instructive. The character of the cyst, whether containing simple cystic fluid or echinococcus, can only be determined by puncture and a microscopical examination. Congenital cysts are simple, or more frequently dermoid, and are produced by an inclusion of the epiblastic layer. We may mistake the condition for solid tumors springing from the orbital walls as exostoses, sarcoma, carcinoma, or for aneurisms, pulsating tumors, or for the cystic changes occurring in tumors from disintegration and softening.

Cystic growths of the orbit should be divided into three classes:

1. Those that originate in either the orbital tissue, periosteum, or from the sheath of the optic nerves. These are cysts pure and simple.

2. Those that arise in some adjacent bony cavity and encroach upon and invade the orbital fossa secondarily. These may arise from the frontal, ethmoid, sphenoid, and maxillary sinuses, the nares and the naso-pharynx.

3. Pathological disintegration and liquefaction of the contents of solid tumors, as sarcoma carcinoma, etc., which may resemble cysts in some respects only.

Each have their distinct history, and an examination will reveal their character and their origin. Cysts of the sheath of the optic nerve are rare and not readily recognizable when small. The abstraction of nutritive

pabulum and the interference with the function by pressure produces in it a pathological descending degeneration, which leads to vascular and later atrophic changes, recognizable in the retinal field by the ophthalmoscope, and decided loss of vision.

Those cysts that arise from adjacent cavities, especially the frontal sinuses, are usually due to an occlusion of the duct, producing an accumulated retention of its secreting contents, over-distending its bony walls, and so encroaching upon the orbital cavity. Direct extension of septic processes to the cavities, producing empyæmas or specific necrosis with growth of tumors, may produce tumors simulating cysts. In the beginning the diagnosis is impossible, and only when marked over-distention of the walls takes place, and its encroachment on the orbital fossa, can a diagnosis be positive. Especially is this true of growths from the ethmoid and sphenoidal sinuses and the maxillary antrum. It is readily seen the vast magnitude the tumors must assume before producing exophthalmos. The displacement of the globe varies according to the direction from which the growth comes; from the frontal it is down and outward. It is interesting to note that the frontal sinuses are not developed to any extent in childhood, and any distention of them will give rise to local manifestations recognizable, while those arising from the deeper fossæ do not. An examination by illumination, nasal and post-nasal, and digital exploration should not be neglected. Interference with the respiratory function and disturbance of speech are significant. If antral tumors are suspected, transillumination in a dark room may be of service. If we have concluded that we have to do with a simple cyst, it should be determined whether it has attachments to the orbital walls or the optic nerve, for this materially influences our treatment. Puncture and injection, drainage and excision, form the procedures for its relief. If we have to deal with a cyst attached to the optic nerve, one is very reluctant in adopting radical means before resorting to the simpler methods. The withdrawal of the fluid and injection of irritating fluids form the simpler means of treatment. The injection of the latter may produce a contiguous inflammation of the optic nerve. The choice of incision, whether subconjunctival or supra-orbital, depends upon the size and location of the tumor. No cast-iron rules can be laid down. If the tumor arises from a neighboring cavity our treatment is a different one, and the attack must be centred to the direct origin. Indiscreetness and over-aggressiveness may result in the loss of the most delicate organ, and judicious action can only be contemplated after a most careful examination of the tumor, its origin and attachments, if any, and, above all, excluding any pathological factor from the neighboring fossa. The patient whose history is recorded is at present under observation, awaiting a trial by the more simpler methods for the relief of his condition.

970 Lexington Avenue.

Cocaine in Chloroform Narcosis.—Rosenberg, at a recent meeting of the Berlin Medical Society, advised the anæsthetizing of the mucous membrane of the nose with a spray of cocaine solution before the administration of chloroform. By this means anæsthesia is more readily induced, and the reflex action on the heart is prevented. Cocaine is an antidote to chloroform, and, therefore, its absorption would probably lessen the danger of the latter.

Senile Heart.—Four cardinal rules with regard to diet: 1. There must never be less than five hours between each meal. 2. No solid food is ever to be taken between meals. 3. All those with weak hearts should have their principal meal in the middle of the day. 4. All those with weak hearts should have their meals as dry as possible.—Balfour.

THE CAUSE AND TREATMENT OF CORNEAL ULCERS.

By S. LATIMER PHILLIPS, M.D.,

Savannah, Ga.

The cornea, from its prominent situation at the forepart of the eyeball, naturally becomes the frequent seat of accident and disease. A goodly portion of these takes some form of ulceration, and it behooves us to be ready to recognize the cause, to remove it, if it is within our power, and to institute a treatment that will arrest the progress of the disease, and bring it to as speedy a termination as possible.

In a paper of the scope of this we cannot go too much into detail, so I shall only glance in a rapid manner at some of the more important causes, which we will divide into constitutional and local.

Constitutional Causes.—Oftentimes we see this condition of corneal ulceration developing in people pulled down by some chronic disease, as phthisis, malarial fever, etc. I know of a case of a man here, far gone in consumption, who by careful attention to his diet, etc., is able to get about and attend to his business; but as soon as he becomes run down from indigestion or overwork, the left cornea begins to ulcerate. He has had several attacks of this mass, and, as a sequel, a large central leucoma with but little vision.

Ulcers of the cornea are much more frequent in the adult and aged than in childhood and youth, if we except that very common affection of childhood, phlyctenular keratitis. Here there appears to be a peculiar dyscrasia, or scrofulous condition, with enlarged glands, eczema of lids, catarrhal conjunctivitis, and tendency to ulceration at angles of lids, nose, etc. Of course where there is lowered vitality the cornea, like other portions of the body, becomes weakened, and the slightest irritation will serve as a starting-point of inflammation, which may progress to complete destruction of the part unless the system is put in a condition to resist the disease. We find in old people sometimes ulceration of the cornea slowly progressing, with no other appreciable cause than lowered vitality. I have seen in the aged ulceration of the cornea after undue straining of the eyes from reading, writing, sewing, etc.

Local Causes.—Anything acting as an irritant to the cornea will serve as a beginning for the ulcer. Foreign bodies of any kind resting on the corneal surface, as pieces of wood, metal, etc., produce abrasions, through which the germs gain access to the underlying tissue, and set up suppurative processes.

Some of the severest cases of corneal suppuration I have met with have been those where the cornea was pierced by beards of grain, with sharp serrated edges. These make a jagged, irregular wound in which the germs easily obtain a resting-place and multiply. I have known stubborn, persistent ulcers easily get well after the removal of an ingrowing lash; this by constant scratching has kept up the disease. Granulation of the lid, too, is not an uncommon cause of corneal ulcer. In a very serious form of this disease we are apt to see more or less complication. A diseased condition of the nose may be a cause also. The germs of the disease passing up through the lachrymal canal. I remember several years ago the case of a man with ozena, the result of syphilis, with destruction of cartilage, and caries of the bones of the nose, who was under my care. He had a central corneal ulcer, sequel to a burn by a small piece of hot iron, and notwithstanding the most vigorous treatment the eye was totally destroyed. Of course acute and chronic catarrh of the conjunctiva play a part in the causation of corneal ulcers. In those severe forms of purulent conjunctivitis we meet with sometimes, where there is so much swelling of the conjunctiva that the corneal nourishment is interfered with, the ulceration varies from a very small point to the suppuration of the whole cornea and its consequent complete destruction.

Treatment.—This I should divide into medical and surgical, and the adoption of one or the other depends upon the state of the ulcer when we find it; oftentimes we have to employ both. Of course where the patient is in a reduced or debilitated condition, tonics must be freely prescribed, the hypophosphites, iron, strychnine, etc. In those scrofulous conditions so often seen in children I prefer the iodides in some form. I usually employ the syr. ferri iodid., and with much satisfaction, together with strict rules as to diet. Cod-liver oil is called for at times, and in old people with delicate stomachs the vin Mariani appears to be a most helpful tonic.

The local medical treatment consists mostly of sedatives in acute ulcers, and stimulants in the indolent kinds. Atropia is useful in all ulcerations of the cornea, save where the ulcer is peripheral and there is perforation or danger of it. Here eserine is called for, but not in too strong a solution (1½ to 1 grain to 1 ounce of water). In a suppurating condition of the cornea hot applications should always be used, water as hot as can be borne to bathe the eye in, or what I have found at times soothing, a decoction of poppy head, a large towel to be wrung out of this and applied over the closed lids, to be repeated at intervals of every few minutes for fifteen or twenty minutes. If dry heat is desirable there is nothing more useful than the Japanese hot box. The box, after the cartridge has been lighted, can be wrapped in a piece of soft cloth and laid over the closed eye. If we find these remedies to fail, then we must resort to surgery.

The one great means which we have at hand, and which can always be depended upon, is the actual cautery, though frequently patients object to its use. But if they should, however, we have another means which in my hands has been most satisfactory. There is nothing in it that appears appalling, nor is it very painful. The treatment I refer to is the application, on a probe, to the entire ulcerating surface, of pure carbolic acid. I believe the late Dr. Williams, of Cincinnati, was the originator of this method. Its application requires care and delicacy of manipulation, for over-doctoring the eye with carbolic acid in its pure state would bring about results most direful. I take a small probe, wrap a thin piece of absorbent cotton tightly around the end, dip it into deliquescent carbolic acid, press out any surplus when withdrawing from neck of bottle, and touch gently the ulcerated surface. Only the smallest quantity is to be used, the acid flowing freely into every sulcus and furrow, however small, and thus coming into direct contact with all the diseased surface. Wherever the acid comes in contact with unhealthy tissue a thin veil of slough forms, which is soon thrown off, leaving the ulcer in a healthy condition, so that in a little time it is filled up with new tissue. This treatment is especially adapted to children with phlyctenular ulcers, for with them hardly more than one application will be necessary, unless the ulcer be very large. It can be made usually without an anæsthetic. The head of the child is held by an assistant while the operator holds apart the lids and steadies the eyeball with thumb and forefinger of left hand, rapidly making application with right. I hardly ever use cocaine, save in a very small child, as the burning is almost nothing, carbolic acid being a well-known obtundent of sensibility.

There is nothing, though, in my opinion, that can fully take the place of the topical application of the actual cautery. This is used principally in the progressive variety of ulcer, though it can be employed with telling effect from the superficial phlyctenular ulcer, through all grades, to the deep, largely sloughing kind. For convenience and elegance I prefer the platinum tips made for the purpose, fitted into a suitable handle and brought to a bright crimson glow by an electric battery. Having the eye cocainized, or the patient under the influence of chloroform, we may cauterize as much as we deem expedient, and we rarely fail to derive benefit from the operation. If the battery is not at hand we can use the bulb-pointed platinum instrument devised by Dr. Grüning, brought to a red heat in an alcohol flame; or even an ordinary strabismus hook may be employed. The difficulty in using Grüning's instrument without chloroform anæsthesia is that after the eye is fixed in position for operation the patient seeing the heated instrument approaching the eye has hardly enough fortitude to hold the eye steady, but moves it away, and the instrument loses its heat before the eye is again fixed. Besides, there has to be an assistant to hold the lamp near the eye. After cauterization the bandage had better be applied, and the regular treatment of atropia, etc., carried out. One application of the cautery will usually be sufficient; but if not, it can be repeated at intervals of three or four days. The greatest care must be observed in this operation not to puncture the cornea. Especially is this so when the ulcer is deep-seated, though if we watch closely what we are doing we can touch thoroughly the parts desired and escape emptying the anterior chamber.

Progress of Medical Science.

Cardiac Irregularity and Obesity.—According to Dr. Kisch, of Marienbad, no functional disturbance in the organism occasions the individual so much anxiety and apprehension as when the regular action of the heart gets disturbed. The educated man is so accustomed from infancy upward to the regular work of his heart, and is so convinced of its supreme importance, that any disturbance of it readily arouses in him the fear that the heart may refuse completely its office. The author has seen medical men who had observed cardiac irregularity in themselves plunged thereby into deep mental depression. There is no reason for this. The author points out that irregularity may awaken apprehensions in grave disease of circulatory or respiratory apparatus, while, on the other hand, it possesses only trifling significance. The author discusses the cardiac arhythmia of obese persons. Slight irregularity is observed in youthful patients with slight heart trouble, especially in young girls who exhibit the anæmic form of lipomatosis. Actual irregularity, in which regular beats and pulses alternate, is seen chiefly in fat people who have already passed their fiftieth year, and in whom other symptoms of heart trouble are present. Complete irregularity, in which pulse-waves alternating in tension and size regularly follow one another, is seen in cases of obesity with marked heart weakness in which there is dyspnœa, angina pectoris, pronounced backward pressure in the venous system, with œdema and dropsy. Kisch holds, in contradistinction to French authors, that simple cardiac intermittency and slight irregularity are not unfavorable as regards prognosis, and these cases may be seen, after a course of treatment directed to adiposity, to recover their pulse regularity. On the other hand, he regards the occurrence of complete irregularity, delirium cordis, as a sign of grave disturbance of the heart mechanism which can never be completely removed, and is sometimes also the sign of suddenly occurring death.—*Berliner klinische Wochenschrift.*

Incoercible Vomiting of Pregnancy.—Apply the continuous current, placing the positive pole on the clavicle, between the two branches of the sterno-cleido-mastoid, and the negative pole over the umbilicus. Use a current of ten or fifteen milliampères for from fifteen to thirty minutes. This method succeeded in five cases in which vomiting was so intense as to render provoked abortion almost imperative.—*Gazette des Hôpitaux.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street

New York, August 24, 1895.

THE STUDY OF CANCER.

ONE of the most interesting problems engaging the attention of medical thinkers and investigators at the present day has to do with the true nature of cancer. What is cancer? Is it a morbid process owing its existence to the presence of a micro-organism in the tissues exciting the cells to an over-activity of growth? If so, is this micro-parasite of the nature of the malarial organism, inhabiting certain localities and being taken into the human body in the water or in the inspired air, or in both? Or may it be transmitted like the parasite of syphilis, directly from the sick to the well? Is the cell stimulation, assuming that there is a plasmodium or a bacterium of cancer, due to direct irritation by the micro-organism, or is it due to the action of a toxin elaborated by this parasite? Or is cancer an inherited vice of cell life and growth, and as presumably independent of a micro-organism as is club-foot? These and a dozen similar questions have been asked again and again since the new views of the nature of infectious diseases have gained acceptance, and while they remain thus far unanswered, it seems not extravagant to hope that the day is not far distant when a solution of some, at least, of the main points of the problem will be reached.

It is not, however, by experiment alone that this question will be settled, for much can be accomplished by intelligent clinical observation. The number of those investigating the subject experimentally is large and ever increasing, and there are among them not a few well fitted, by trained habits of scientific research and by freedom from preformed opinion, for the work they have undertaken. But they can be assisted greatly by those general practitioners, especially country practitioners, who have lived and worked all their lives in one community, and who know the medical histories of every family for perhaps three or four generations.

In a paper read before the Oxford Branch of the British Medical Association, Mr. D'Arcy Power, to one of whose interesting experiments in relation to the etiology of cancer we referred not long since, speaks of the assistance the general practitioner may give those who are trying to work out the problem from a scientific standpoint. In the first place, he says, the influence of heredity should be ascertained in every case of cancer, the inquiries being made in reference to the collateral as well as to the lineal descent. The family diathesis on the parents' side should be noted, for it is still undecided how far, if at all, the various manifestations of the arthritic diathesis are associated with cancer. Then, again, there is the question of the soil and water in any locality where cancer appears to prevail to an unusual extent. Reports of "cancer houses," that is, of houses several successive inmates of which, unrelated to each other, have died of cancerous disease, are interesting; they may possibly also become instructive when a sufficient number of them, giving details of soil and water-supply, of age, occupation, and antecedents of the successive occupants, etc., have been collected. In thus collecting data general practitioners may aid greatly in the solution of the perplexing, and for that very reason most interesting, problem of the pathogenesis of cancer.

SCIENCE AND THE FRENCH DRUGGIST.

THERE has been a great deal of vague writing on the subject of phosphates, hypophosphites, and the various other phosphorous compounds. A very general impression exists in the profession that these preparations have some value in medicine, but we are not aware that there yet exist substantially established clinical facts which demonstrate that phosphates or phosphites do any good whatever. What is a common belief and common practice, in the medical profession of to-day, has, however, probably some substantial basis. A distinct "boom" was given to the phosphorus compounds by the introduction of the hypophosphites, and the extreme claims made for these preparations at the time of their introduction are still remembered by many. Physicians, however, have very largely forsaken a strict adherence to the phosphite compounds and prescribe phosphates and phosphorus solutions in their place with apparently much the same effect.

A year ago Dr. Albert Robin read a preliminary communication before the Paris Academy of Medicine upon the therapeutic use of the glycerin-phosphates, which up to that time, he said, had never been useful as medicinal agents. He may perhaps have been mistaken on this point; at least we are informed that a good many years ago there was sold in this city under the name of "protogon," a phosphorous compound, which was really a glycerin-phosphate. This protogon was extolled as a new discovery of extraordinary value in nervous and wasting diseases of all kinds, but the bottom fell out of "protogon," as it has of so many other secret or proprietary remedies which are not advertised with sufficient persistence.

M. Robin asserts that his new preparation has occupied his attention for the past six years, and he believes that there is a great future for it, because he thinks it exercises an elective action upon the nervous system. He has made a study of the nutritive conditions, particularly in neurasthenia, and he believes that in this disease, among other things, there exists an exaggerated consumption of the lecithin of the nervous centres. On the other hand, he finds that the ordinary medicinal phosphates supply this need in a very imperfect way. Dr. Robin gives, in the *Bulletin Général de Thérapeutique*, an account of a long series of experi-

ments which he has made upon the nutrition as influenced by different drugs, and particularly by the phosphates. His article is accompanied with many tables which have a most scientific appearance, and give evidence of a very great amount of chemical and physiological work. We have not space for any detailed description of the experiments. Dr. Robin, however, concludes his study with certain propositions which he considers have been demonstrated.

These are, first, that the glycerin-phosphates given by subcutaneous injection accelerate the metabolic changes of the organism, affecting both the organic and the inorganic substances, but particularly the latter. Though accelerating principally disintegrating changes, they act in all the stages of physiological metabolism. In other words, they favor both the assimilation of albuminous matter, and its cellular integration and disintegration. They influence but little the formation of uric acid. They act upon the sulphur compounds and increase the oxidation products. The result is that the organs rich in sulphur, like the liver particularly, become the seat of more active nutrition under the influence of these wonderful glycerin-phosphates. They have no marked effect upon the intestinal fermentations. They increase the excretion of chloride of sodium; they favor, probably, the assimilation by the nervous system of the phosphates of the food, and they moderate the waste of the nervous system, acting upon these centres as a protection and fixing the materials of the nervous centres more firmly. They increase the changes in the calcium compounds and the other salts that go to form bony tissue, without influencing the changes in the phosphated compounds.

We observe that all these remarkable effects upon the nutrition of the nervous system are accompanied with an inset advertisement of the glycerin-phosphates of Robin as prepared by certain skilled Parisian druggists. In other words, coincident with the appearance of Robin's article, is a very conveniently placed announcement of where you can get the effective preparation. We confess to some serious doubts about the value of the glycero-phosphates, despite the elaborate chemical tables and laborious physiological analyses of M. Robin. If he has got a good thing, it is a pity that he has united the commercial and scientific aspect of it in such an ingenious fashion.

A MENACE TO THE COUNTRY'S HEALTH.

Every summer the eastern seaboard of this country, from New Orleans to New York, is threatened with an invasion of yellow fever by vessels hailing from Cuban ports, especially Havana and Santiago. Our only defence against this invasion lies in a quarantine service which varies in efficiency at different points, and which may fail at any time in one of a dozen ports through a single error in judgment of the executive officer. This is a very weak defence, as the country learns to its cost every few years; yet as long as Cuba belongs to a foreign power, and that one which ranks low in the scale of practical sanitation, so long shall we be menaced with every returning summer. The only way to escape the danger is to stamp out the plague in its home. There is no more reason why yellow fever should be endemic in Cuba than in Jamaica. Kingston, in Jamaica, was once a pest-hole, now it is a health-resort. Havana, Santiago, and dozens of smaller places along the Cuban coast could be made as healthy as Kingston if the Spanish authorities would undertake the task. But they never have, and they never will, if we may judge from the way they have neglected their duty in this respect in the past. Sanitarians, therefore, can scarcely help sympathizing with the revolutionists who are struggling for the freedom of their native island. The manifest destiny of the island appears to be to enter the federation of American States, and this result will doubtless be hastened by the success of the revolution. When once it is a part of this country, the government will see to it that this breeding ground for the yellow scourge is cleaned and garnished, and one more victory will be won for the cause of sanitation.

News of the Week.

Fatal Quarrel Between Surgeons.—Two surgeons of Portland, Ore., who had formerly been partners, quarrelled over an operation performed by one of them at the city hospital, and shot each other fatally.

Yellow Fever still prevails extensively in Cuba, and appears to be steadily increasing. Most of the victims are the unacclimated soldiers from Spain who are fighting the revolutionists.

The Late Professor Huxley.—It is proposed to establish a memorial to the late Professor Huxley, which shall take the form of an annual lecture and science scholarship and medal, at the Charing Cross Hospital Medical School.

Dr. Salomon Moos, Professor of Otology at the University of Heidelberg, died recently at his home in that city. He was born at Randegg, in Baden, July 15, 1831.

Dr. Thomas McKennan, of Washington, Pa., died at his home in that place on August 9th. He was born in 1824.

Surgeon-General James R. Tryon, of the navy, has been elected a member of the Red Cross Society of Venezuela. He has also been awarded the bronze medal of that society in recognition of the services he rendered the wounded at La Guayra during the revolution of 1892, when Dr. Tryon was attached to the flagship Chicago.

Henry Dunant, the founder of the Geneva Red Cross Society, is now, it is reported, at the age of sixty-seven, in great poverty and nearly starving. He spent all he had in promoting his idea.

Dr. Charles F. J. Lehlbach died at his home in Newark, N. J., on August 14th. He was born in Baden in 1835, and came to this country when fourteen years of age with his father, the Rev. Frederick Augustus Lehlbach, who took charge of a German church in Newark. Dr. Lehlbach was graduated from the College of Physicians and Surgeons in this city in 1856, and practised in Newark until the war. He enlisted at the beginning

of the civil war and served until its close, when he returned to Newark and built up an extensive practice.

In Memory of Dr. Danielssen.—A memorial tablet of the late Dr. Danielssen, designed by Max Klein, of Berlin, has been placed on the front of the Lungegaards-Hospital at Bergen.

The Continental Anglo-American Medical Society held its annual meeting in London on August 2d, at the Savoy Hotel, under the presidency of Sir Richard Quain. Five new members were elected, and the Secretary, Dr. Barnard, of Paris, stated that the total membership in the Society had now reached ninety-six. After the meeting those present sat down to a luncheon. After the toast "The Queen and the President of the United States" had been drunk, Sir Richard Quain proposed "Prosperity to the Society," expatiating on the need supplied by such a body. Responding to the toast of "Our Guests," Mr. Ernest Hart expressed his pleasure at having an opportunity of meeting such a representative gathering of British and Americans practising on the Continent. The Society was one which had a very useful future before it, and he wished it a career of ever-growing usefulness and prosperity. The address of Dr. Barnard, the Secretary of the Society, is 362, Rue St. Honoré, Paris. The next meeting will be held at the same time and place as that of the British Medical Association.

British Laryngological, Rhinological, and Otological Association.—The annual summer meeting was held on July 25th and 26th, Dr. W. McNeill Whistler, President, in the chair. A discussion on the Surgical Treatment of the Accessory Cavities of the Nose, was opened by Dr. J. N. Mackenzie (Baltimore), who dealt with Empyema of the Antrum of Highmore. He was in accord with Freeman, who opened below the nasal duct, but considered that the opening by an alveolus was required in all but recent cases. Dr. Luc (Paris) dealt with Disease of the Frontal Sinus. His method of operation consists in opening wide by the anterior wall of the sinus, and establishing a free communication with the nose by means of an india-rubber drain. Dr. Bryson Delavan (New York) confined his observations to Ethmoidal Disease; and Dr. F. H. Bosworth (New York) said his favorite method of gaining access to the cells after removal of the anterior end of the middle turbinal, was by the use of a drill. Dr. W. H. Daly (Pittsburg), Dr. Roaldes (New Orleans), Mr. Mayo Collier, and Dr. Dundas Grant, continued the discussion. The subject of the treatment of Laryngeal Stenosis was opened by Dr. Sajous (Paris), who dealt with the stenotic conditions of the infra-glottic space. A paper on this subject by Professor Massei (Naples) followed. On July 26th Dr. Krause (Berlin) and Dr. Heryng (Warsaw) opened a discussion upon the Surgical Treatment of Laryngeal Tuberculosis, and described their methods of treatment by curettement and the application of lactic acid. Dr. Gleitsmann (New York) stated that he had adopted, with certain slight modifications, the methods originated by Heryng and Krause. Dr. Sims Woodhead introduced a discussion upon the Antitoxin Treatment of Diphtheria, and described his views and experiences as gained from an investigation of 2,000 cases. He supported the treatment not only for diphtheria, but also as a prophylactic against its occurrence in those exposed to infection. Mr. L. Browne, Dr. Macintyre, and Dr. Roaldes closed the discussion. The Society dined at the Langham Hotel on Friday night, and a very successful meeting was then concluded.—*British Medical Journal.*

The First Chinese Woman Doctor.—An item is going the round of our exchanges concerning a Dr. Hu King Eng, recently graduated in Philadelphia, who is said to be the first Chinese woman to acquire an American medical degree. This is incorrect, for she was preceded by Dr. Y. May King, who was graduated in this city several years ago, and has since been in practice in Kobe, Japan. Recently Dr. King married Mr. H. Eça da Silva, and went with her husband to Honolulu, where she now resides.

The Woman's Medical Journal, not to be outdone by its contemporaries, has begun the publication of portraits and biographical sketches of the women of the profession. Concerning the first portrait, the *Journal* says that it "shows a young woman with a strong and bright face, a face that shows determination to succeed, and to succeed because success means not only much for her, but because it helps every other woman, not only the woman of to-day, but the vast army of to-morrow, who are waiting now, learning what to do and when and where they may serve the world best." To which it is our pleasing duty to add that the face is not only strong and bright, but comely as well. We predict for our esteemed contemporary a rapidly increasing circulation.

To Prevent the Spread of Cholera from Mecca.—Dr. Saleh Soubhy, in a recent work on the Mecca pilgrimage, offers the suggestion that as cholera reaches Mecca from the south, it should be arranged throughout the Mohammedan world that pilgrimages to Mecca from the north and from the south should take place only on alternate years, so that the two sets of pilgrims should never touch or intermingle.

The American Dermatological Association.—The nineteenth annual meeting of this Association will be held at the Windsor Hotel, Montreal, Canada, September 17, 18, and 19, 1895. The *President* of the Association is Dr. S. Sherwell, of Brooklyn; *Vice-President*, Dr. J. A. Fordyce, of New York; *Secretary and Treasurer*, Dr. C. W. Allen, of 640 Madison Avenue, New York.

A Portuguese Medical Congress is being organized by the Sociedade de Sciencias Medicas. It will be held in Lisbon.

Australian Medical Students.—The total number of students in the Medical Faculty of the University of Sydney during 1894 was one hundred and nineteen.

Diphtheria is increasing in London, but the mortality from the disease is decreasing.

The Jenner Centenary in Russia.—In commemoration of the centenary of vaccination, the Russian National Health Society proposes to offer four prizes for the best works on vaccination; to collect and publish materials for a history of the practice of vaccination in Russia, and also a short history of the same in Western Europe; to publish a Russian translation of Jenner's

works, with his biography and portrait; to organize an exhibition of objects connected with vaccination; and finally, to hold a commemorative meeting on May 14, 1896.

The Kansas City Medical Record has appropriated twelve columns in its August issue from the MEDICAL RECORD without giving any credit therefor. We are ashamed of our namesake.

The City of London and the British Medical Association.—It was thought that the corporation of the city of London would extend its hospitalities to the members of the British Medical Association during the late meeting, but it did not. It entertained the son of the Ameer of Afghanistan, but said it would cost too much to feed the doctors. Even a request that the Association have the use of the Guildhall was granted only on condition that the Association furnish the necessary expenses. The offer was declined with thanks.

A Parisian Medical Quarrel.—Drs. Proust and Roux are at present engaged in a bitter controversy concerning the merits of the diphtheria antitoxin. A child died soon after receiving an injection of antitoxin, and Dr. Proust said that the death was due to the remedy. No autopsy had been made on the child, and Dr. Roux naturally declaimed against the assumption that the antitoxin was to blame. The controversy has grown so acute that some of the participants even forget their patriotism and assert that the antitoxin treatment is a German discovery anyway, and Roux simply appropriated it without warrant and proclaimed it as his own.

Noble Tattooed Men.—According to a writer in the *Lancet-Clinic*, the Duke of York, his uncle, the Duke of Saxe-Coburg-Gotha, the Grand Duke Alexis, and many of the English nobility, have had themselves tattooed with flags, initials, coats-of-arms, and other designs.

French Brandy.—Dr. Laborde recently read a paper before the Académie de Médecine of Paris on the liquor supplied to the French army under the name of cognac. He had analyzed the stuff used for making the worst spirit into the best cognac, and found that it consisted of castor-oil, cocoanut-oil, and other fatty substances treated with nitric acid and labelled "Bouquet de Cognac." "Pure Jamaica rum," sold by an English house, proved, on analysis, to be much of the same quality.

Pasteurized Vichy is advertised for sale in a Broadway drug-store. A fortune awaits the man of enterprise who will provide aseptic oysters next month.

Kiel and Rostock are the only German universities which have no psychiatric clinic.

The Meeting of the British Medical Association was not so largely attended as was at first announced. It was thought that the number of those present would reach six thousand, but the official record shows that the attendance was under three thousand.

London Doctors and Advertising.—The English medical man is nothing if not ethical, and few things shock him so much as the way in which he imagines his American confrères keep themselves before the public. The Londoner seems, however, to have made hay while the sun shone during the week of the British Medical Association. One of the daily papers had columns of biographical notes on the metropolitan physicians and surgeons, prominent and otherwise, the details of which could hardly have been obtained from any but the subjects themselves, and the photographs of the same individuals were exposed for sale in many of the shops along the Strand, in company with those of royal personages, actresses, and other celebrities.

Tri-State Medical Society.—The seventh annual meeting of this Society will be held in Chattanooga, Tuesday, Wednesday, and Thursday, October 8th, 9th, and 10th. A large attendance is expected.

The Effect of Ovariotomy upon the Voice.—The well-known effect of castration in young males in heightening the pitch of the voice has led Dr. E. J. Moure, of Bordeaux, to investigate the effect of ovariotomy upon the voice. His observations in two cases of ovariotomy in young women showed an effect exactly the opposite of that of castration in men, since the voice became deeper and harsher, and the patients thought they were hoarse. The higher notes were lost and the voice fell from soprano to mezzo-soprano. This small number of observations is obviously entirely insufficient to establish a fact; and as no previous cases are on record of the production of any changes in the voice by ovariotomy, the observations must await confirmation from further cases.—*Boston Medical and Surgical Journal.*

The Metric System in England.—A committee of the House of Commons has made a report, which will be voted upon at an early date, in favor of the adoption of the metric system in England. It would have its use made immediately legal, and obligatory after an interval of two years. As a preparation for the change it would make the metric system a compulsory part of teaching in all public schools, "as a necessary and integral part of arithmetic."

La Technologie Sanitaire is the title of a new sanitary journal published in Louvain.

The Medical Faculty of Harvard University has voted to authorize approved physicians having the necessary facilities and desirous of teaching its medical students, to announce their courses yearly in the Medical School.

Treatment of Soft Corns.—Mr. Philip Miall writes to the *British Medical Journal* that a concentrated solution of tannin, made by dissolving an ounce of perfectly freshly made tannin in six drachms of water with the aid of gentle heat, gives immediate relief to soft corns, if applied once or twice a day between the toes after washing. Tannin in powder is not quite so effectual.

The Lancet as a Chromo.—An enterprising accident insurance concern in London has issued circulars to medical men in England, offering a subscription to *The Lancet* in conjunction with an accident policy. Our esteemed contemporary assures its readers that it cannot approve of this scheme, with which it is in no way connected, and of which it was wholly unaware until one of the offensive circulars came into its possession.

Clinical Department.

THE EFFECT OF REMOVAL OF THE OVARIES UPON THE SEXUAL APPETITE.

By A. LAPTHORN SMITH, M.D.,

MONTREAL, CANADA.

Miss X——, twenty-five years of age, consulted me this morning for a discharge, which on examination proved to be gonorrhœa. She gave me the following history: She had had her ovaries and tubes removed about seven years ago by another surgeon, on account of pain and enlargement in them. I saw her a few months afterward, when she consulted me for troubles of the artificial menopause, through which, however, she passed successfully. I then lost sight of her until to-day, when she told me that her menstruation had gradually left her, until the end of the year, when it disappeared entirely, so that she has had no periods during the last six years. She went to Boston three years ago and returned to Montreal last month, when she met a former male acquaintance and had intercourse with him. During this act she became very excited, having an orgasm, and straining herself, which she thinks is the cause of her discharge. On further inquiry she assured me that she never had experienced so much sexual pleasure as she did this time, and in her opinion the removal of the ovaries in no way alters the feelings of a woman toward the opposite sex.

This, of course, is not the general belief, and I therefore think it well to report this case as one among many others in which the removal of the ovaries has not been followed by loss of sexual desire, but, on the contrary, by a marked increase of it.

250 Bishop Street.

A CASE OF TETANUS CURED WITH ANTITOXIN.[1]

By C. F. TIMMERMAN, M.D.,

AMSTERDAM, N. Y.

About ten years ago, I read a paper on tetanus before this Society, and at that time I devoted considerable time to the etiology of the disease, and gave the opinion of our best authorities prevailing at that time. Lockhart Clark expresses the opinion that tetanus depends, first, upon an excessively excited state of the nerve-tissue of the cord, induced by hyperæmia and morbid conditions of the blood-vessels and exudation, and disintegration resulting therefrom. Second, that the spasms are the result of the persistent irritation of the peripheral nerves, by which the exalted excitability of the cord is aroused, and thus the cause which at first induced in the cord its morbid susceptibility to reflex action is subsequently the source of that irritation by which the reflex action is excited. Another states that a large percentage of cases of tetanus is caused by injuries to the peripheral nerves due to compression. To-day, thanks to some of the observers, as Rosenbach, Nicolaier, and Kitasato, the specific bacillus has been discovered. Carle and Rattone, in 1884, furnished the first proof of the communicability of the disease by inoculation of rabbits with pus from a wound, in a case of human tetanus. Nicolaier, in 1885, found disseminated in all kinds of earthy matter bacilli which, introduced subcutaneously into mice, guinea-pigs, and rabbits, produced typical trismus and tetanus with fatal termination. Rosenbach, in 1886, demonstrated the tetanus bacillus for the first time in man. Thus was established the generic relation to the diseases of the bacillus of Nicolaier. The poison appears to be in the ptomaines, a specific product of the tetanus bacillus. Kitasato observed that the filtrate, perfectly free of germs, produced the same tetanic effect. Since wounds of the most trivial nature are as apt to be followed by the disease as those more serious, it stands us in hand to be on our guard at all times.

In the treatment of this disease, since such poor results have been attained with the old remedies, I think the hope of successful treatment lies in the use of antitoxin.

I have been unfortunate enough to have had three cases of tetanus.

Case I.—J. R——, a Pole, aged thirty-four. On the evening of October 16, 1885, he was injured in a railroad accident, and remained near the track all night. Fourteen hours after the injury, I found him with the foot crushed, two scalp wounds, and many cuts and bruises on the face, arms, and hands. I dressed the wounds and he received the best attention, the wounds healing very kindly. On the eighth day the first symptoms of tetanus were present. He died on October 25th, nine days after the accident.

Case II.—J. S——, a Pole, aged twenty-six. He was injured in a mill, his arm being terribly lacerated from the middle third of the humerus to the wrist, with fracture of the humerus at the middle third. I dressed the wounds, placing the entire arm in a metal trough, using hot-water dressing and antiseptics. I can truly say I never saw a wound improve better than this did, but on about the twelfth day that sardonic grin caused wrinkles on my own countenance, and in spite of all the well-known remedies, and the assistance of the hospital staff and nurses, he died on the nineteenth day. At autopsy I found a sharp fragment of the broken bone imbedded in the median nerve. I was then about satisfied that this was the principal cause of the trouble.

Case III.—William W——, an Irishman, aged nineteen, burned by his clothes catching fire from a lamp, on the evening of April 28, 1895. The entire left side from the sternum to the spine, and from near the spine of the ileum to the base of the neck, and the entire arm from near the wrist to the base of the neck, including the axilla, and also both hands and fingers, were burned deeply, in some places to the bone. When I arrived at the house, about 2 A.M., I found what is commonly known as a potato poultice applied. (The entire wound was covered with scraped raw potatoes, fresh from the cellar—a most excellent habitation for the bacilli of tetanus.) I removed as best I could all this material and applied Carron-oil dressing. I again dressed the wound the next morning, removing all that remained of the poultice, considerable of the burned skin coming with it, opening the blisters and pressing the skin down gently. All went well, the wound acting very kindly.

Nothing occurred to cause alarm until May 15th, seventeen days after the accident, when the man complained of some stiffness of his jaw, which he said he had felt for two or three days. I lost no time in writing to Dr. Paul Gibier, of the Pasteur Institute, New York City, who promptly replied and advised me to use antitoxin immediately, also stating that he had never cured tetanus in a human being, but had in a number of horses. At the same time I did all I could to relieve the advancing tetanic symptoms. I gave sulph. physostigma hypodermically, grains, 1 to 100, twice daily, and by mouth every three hours. Later I increased it to grains 1 to 50 each dose, and I gave morphia as indicated, and chloral very freely, sometimes 30 grains, repeated every two, three, or four hours. The spasms were at first so well controlled by these remedies that it was not until Tuesday morning, May 21st, three weeks after the injury, I used the antitoxin. There was an apparent fixation of the muscles of respiration, and he was almost unable to breathe; nearly all the muscles were in a constant state of spasm. I admin-

[1] Read before the Montgomery County Society, June 12, 1895.

istered anodynes with a more free hand and with the family's consent. The patient then grew so much worse I availed myself of the only remaining chance, and tried this remedy. I gave the first injection of 25 c.c. (about 6 drachms) tetanus antitoxin, in the lateral part of the abdomen; the serum was very rapidly absorbed, and at 10 P.M. I gave another 25 c.c. The following morning I gave 10 c.c., and intended to give the remaining 15 c.c., but he was so exhausted I waited until the next morning. I wrote to Dr. Gibier, who advised me, as the treatment was begun so late, to give him more serum, and also to wash the wounds with Gram's solution (iodine, 1 gm.; iodide of potassium, 2 gm.; and distilled water, 300 gm.). On Monday morning, May 27th, I injected 10 c.c. more of the serum, and in the evening 15 c.c., when the spasms were almost subdued. I waited for more symptoms to appear to use the other bottle, but there was no use for it, and I relied only on chloral afterward. The present condition of the wound is most excellent, everything healing very rapidly, and patient sitting up most of the time. In looking over recent publications I find only six or seven cases in all where antitoxin or tetonine has been used successfully in tetanus, and they were all by foreigners, and I believe this is the first case in America where antitoxin has saved a human being.

A CASE OF ACUTE ATROPHY OF THE LIVER.

By W. KIRKER BEATTY, M.D.,

LONG ISLAND CITY, N. Y.

LATE RESIDENT PHYSICIAN ASTORIA HOSPITAL, LATE INTERNE EMERGENCY HOSPITAL, WASHINGTON, D. C.

According to Bartholow the term acute yellow atrophy of the liver means "an acute affection of the liver characterized by a rapid wasting or degeneration of the organ accompanied by the systemic symptoms belonging to an acute acholia or cholæmia." According to Murchison, "acute atrophy of the liver is probably but a symptom of some blood-poisoning. The liver becomes rapidly atrophied with the development of jaundice and cerebral symptoms, what remains of the organ after death is found to be extremely soft and yellow, with no appearance of lobules and with the secreting cells in a great measure broken up into granular matter and oil-globules."

The following is the history of the case from the date of entrance to the hospital to death, which occurred three days later, including as much of the antecedent history as could be obtained.

April 17, 1895, I admitted to the wards of the hospital M. B——, aged thirty-five, white; female; American by birth. Has had nine children, seven of whom are living and healthy. Last confinement had occurred sixteen months previous. A probable one or two months' pregnancy existing. Her antecedent history showed her to have been a strong, healthy woman, with no hereditary predisposition, though her mother died of a disease which strongly resembles in description this one. Her hygienic surroundings were of the worst, poverty with its squalor and privation of nourishing food. The husband, a painter, kept his kit and paints in an outbuilding, so that little influence could be attributed to them.

The first symptoms of the present illness were observed April 11th, when she complained of slight backache. The following morning symptoms of acute gastro-duodenal catarrh presented themselves, pain in the epigastrium, anorexia, nausea, vomiting, bitter taste in the mouth, headache (which was very persistent), and general malaise. Icterus was probably existent to some degree, but was not noticed by the husband, who being a working man seldom saw his wife save by lamplight. April 13th, all symptoms save that of the persistent headache were relieved, and on the next day, Sunday, she felt well enough to be up. But on Monday marked icterus set in and the patient rapidly grew worse, until Wednesday the 17th, when she was admitted to the hospital in the following condition: Temperature, 37.8° C. (99° F.); respiration, 52, and pulse, 150, scarcely perceptible. She tossed about constantly in a state of active delirium. Her skin was hot, dry, and harsh, perspiration having been entirely checked. The entire body was jaundiced, the color being more intense on the upper part. Tongue dry, brown, and glazed smoothly: teeth encrusted with sordes; lips discolored from capillary hemorrhages. The mucous membrane lining the nasal passages was stained with dried blood and discolored by capillary hemorrhages. Shortly after admission she vomited, the matters ejected containing mucus and blood. There was an involuntary passage of colorless, watery, and foul fæces. On catheterization eight ounces of urine were obtained, which when examined was found to be of a very dark golden brown color, specific gravity 1.020, acid reaction, a large amount of albumin, and devoid of chlorides and phosphates. Physical examination of the hepatic region elicited pain on pressure; on palpation no part of the liver could be felt although carefully sought for; on percussion hepatic dulness extended but two inches below the nipple, below the hepatic dulness tympanites was found. Splenic dulness was slightly increased, but the intestines were so distended that this was not easily determined.

The history subsequent to this was that of progressive decline from the active delirium to low muttering delirium, tremors, subsultus tendinum, carphologia, stupor, coma, and death due to exhaustion of all the vital forces. Briefly it is as follows: By 8 P.M. the pulse had gained in strength and diminished in rate, being 140; respiration had decreased to 40; temperature had risen to 38.7° C. (101.6° F.). The temperature apparently rising as delirium increased.

April 18th.—During the night the noisy delirium merged into a condition of stupor from which the patient could be partially aroused by shouting in her ear. 8 A.M., the pulse was 128, the temperature had risen to 39.5° C. (103° F.). Skin was more moist, and the icterus of a darker shade about the head and upper part of the trunk; the extremities slightly lighter. 1 P.M., pulse imperceptible; respiration, 44; temperature, 37.2° C. (99° F.). 8 P.M., pulse again perceptible, being 160; respiration, 44; temperature, 39.2° C. (102.6° F.). Extremities cold and moist. 11 P.M., a hemorrhagic discharge from the uterus occurred, but nothing definite could be ascertained on examination; in all probability it was a one or two months' conception.

April 19th.—During the night vomiting occurred frequently, the vomitus consisting of the ingesta, mucus, and blood. The pulse-rate and strength had improved, being 120; respiration continuing uniformly at 44.

The patient was rapidly drifting into a very low typhoid condition; she was constantly sinking down in bed, muttering, hands trembling, and ceaselessly picking at the bedclothes, etc. Mouth was constantly open, as if the muscles were too weak to close it; tongue dry and glazed, with a smooth dark brown coating; lips more discolored from capillary hemorrhages; breath heavy and foul. Bowels had several involuntary movements during the night, the stools being light in color and of large quantity. Pupils very much dilated and not responding to bright light nor to pilocarpine which had been injected several times. Color of the skin seemed to be of a lighter shade. Pulse, 150; respiration, 48; temperature, 38.1° C. (100.6° F.). At 1 P.M. the pulse was 128; respiration, 46; temperature, 38.7° C. (101.6° F.). At 8 P.M., the lower delirium merged into coma; mucous râles over the entire chest were heard.

April 20th.—During the night the coma gradually deepened. Pulse weaker though slower, being 106; respiration, 56; temperature, 38.2° C. (100.6°) F. The bowels ceased to move. At 1 P.M. the respirations increased to 65. Died comatose at 5 P.M.

The treatment was wholly symptomatic and tentative, as the patient was practically moribund when brought in. Efforts were made to produce diaphoresis by hot packs, fluid extract of jaborandi by mouth, and hypodermic injections of muriate of pilocarpine, but with no apparent effect, though as much as one-third of a grain was used. To keep the bowels open magnesium sulphate and the mild chloride of mercury were used. Free and bold stimulation was employed throughout, most reliance being placed on nitro-glycerine, which was given by hypodermatic injection hourly in $\frac{1}{100}$ grain doses. Strychnia by hypodermatic injection was used every four hours without apparent effect, so was discontinued. Digitalin $\frac{1}{75}$ grain was also tried with no result. The nourishment for the first day was milk, but this being vomited before digestion could be effected, I substituted bovinine with success.

Autopsy.—An autopsy was made but permission could be obtained to examine the abdominal viscera only. Body well nourished and muscular. Deeply jaundiced hue of the entire body including all the abdominal viscera. No scars on the genitals nor in the groins. A layer of fat, one inch thick, deeply bile-tinged, covered the abdomen. Serous covering of the intestines greatly congested. Stomach and intestines much distended with gas. The liver was hidden by distended intestines, the lower edge being above the margin of the ribs; about two inches only of the liver was opposed to the thoracic wall. The organ, on account of its friability, was detached with some difficulty in order to remove it intact. The volume was reduced at least one-third, but as there was no facility at hand for weighing we could not make a more accurate estimate. It was quite friable and flabby, the surface somewhat wrinkled and splotched with greenish-yellow patches. On section a dark greenish substance oozed. Bile-ducts were patent, but the gall-bladder was much diminished in size and capacity, and empty, save for a small amount of inspissated mucus. Spleen, much enlarged, very soft and friable. Dark greenish red on section. Kidneys, jaundiced and somewhat enlarged, rather soft and flabby. Much fibrous tissue in its substance. Pancreas, jaundiced, very much indurated and enlarged; adherent to all surrounding tissues; resistant on section. Appendix vermiformis, calibre narrow, admitting only small probe. Uterus, slightly enlarged.

The following is a chronological list of all cases reported in America:

TWIN-BIRTH—ONE CHILD DEAD, THE OTHER LIVING.

By HENRY HEIMAN, M.D.,

NEW YORK.

ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE MT. SINAI HOSPITAL DISPENSARY.

MRS. S——, aged twenty-eight, married seven years, had two living children and three abortions. I was called to see her on March 31st, and found her in labor pains. On vaginal examination I was surprised to make out, instead of the usual presentation, a sharp irregularly circular edge of bone, extending backward from which the examining finger could map out a soft, pulpy mass. After a few sharp pains a dead fœtus was delivered. It was of a grayish color, skin macerated in different spots; the upper and lower extremities were flattened, probably from pressure; the cranial bones easily compressible and freely movable; cranial cavity nearly empty. On my first examination I did not find the membranes which should have contained the dead fœtus. Three hours after delivery of the dead fœtus a living child was expelled. There was no history of any vaginal discharge at any time during pregnancy.

Parvin gives the following varieties of dead fœtus: "1. Liquefaction generally occurring during the first or second month of pregnancy, *e.g.*, fleshy mole. 2. Mummification: In this variety the fœtus appears as though it had been preserved in alcohol. 3. Maceration: In this variety the fœtus appears swollen, its form changed, abdominal cavity often distended, bones of the cranium move freely upon pressure, the epidermis comes off in large flakes; odor is not pleasant, but not like putrefaction." My case seems to correspond with this type, the fœtus having lived up to the fourth month. "4. Putrefaction, caused when membranes rupture and accompanied with general symptoms of putrefaction." The patient made an uninterrupted recovery, and the living child is doing well.

220 EAST 116TH STREET.

Rise of the Medical Profession.—During early mediæval times the monasteries, serving as centres of instruction, gave some embodiment to the medical profession, like that which our colleges give. In Italy there later arose institutions for educating physicians, as the medical school of Salerno, in 1140. In France, before the end of the thirteenth century, the surgeons had become incorporated into a distinct college, following, in this way, the incorporated medical Faculty; and while thus integrating themselves, they excluded from their class the barbers, who, forbidden to perform operations, were allowed only to dress wounds, etc. In our own country there have been successive consolidations. The barber-surgeons of London were incorporated by Edward IV., and in the fifteenth century the College of Physicians was founded, and "received power to grant licenses to practice medicine—a power which had previously been confined to the bishops." Progress in definiteness of integration was shown when, in the time of Charles I., persons were forbidden to exercise surgery in London and within seven miles, until they had been examined by the company of barbers and surgeons; and also, when, by the eighteenth year of George II., excluding the barbers, the Royal College of Surgeons was formed. At the same time there have grown up medical schools in various places, which prepare students for examination by these incorporated medical bodies; further integrations being implied. Hospitals, too, scattered throughout the kingdom, have become places of clinical instruction, some united to colleges and some not. Another species of integration has been achieved by medical journals, weekly and quarterly, which serve to bring into communication educational institutions, incorporated bodies, and the whole profession.—Herbert Spencer, in *The Popular Science Monthly.*

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-third Annual Meeting, held in London, July 30 and 31 and August 1 and 2, 1895.

(Specially Reported for the MEDICAL RECORD.)

SECTION IN MEDICINE.

FIRST DAY, WEDNESDAY, JULY 31ST.

Discussion on Diphtheria.—This discussion embraced the following points: 1, Pathology of diphtheria and its sequelæ; 2, symptoms and progress; 3, statistics of mortality under the antitoxin treatment and under other treatment; 4, effect of the antitoxin treatment upon the local affection, upon the general condition, and upon the sequelæ; 5, effects that may arise from the antitoxin treatment.

DR. SYDNEY H. C. MARTIN, in opening the discussion, said that although the idea was combated for a long time even by eminent men like the late Dr. Murchison, it is now definitely established that there exists a number of micro-organisms intimately connected with the various diseases, and that each disorder has its specific organism, which may sometimes also be found elsewhere. Pasteur laid the foundation of the theory when he discovered that micro-organisms could be artificially cultivated outside the body, and that when these culture-products were inoculated in an animal, such as a rabbit or a guinea-pig, they gave rise to a disease of the same kind as the one from which the original germs had been derived. Bacteriology is not merely an abstract science devoid of practical application, for numerous experiments have proved the existence and character of a number of micro-organisms and determined the part they play in the causation and progress of disease, and within the last few years it has been proven that it is possible to prevent their development. But how to prevent the spread of disease is only one of the discoveries that we owe to the science of bacteriology. It has been demonstrated that inoculation with a cultivated micro-organism will produce a milder form of a disorder. The attenuation of these micro-organisms can be effected by causing them to pass through the system of some animal, or by an artificial culture in various media.

The pernicious effects due to the presence of a micro-organism are referable, not to the action of the bacilli themselves, but to the poisonous effects of the products to which they give rise. Antitoxin is derived directly from the toxin produced by the bacillus, whether in or outside the body, and is separated from the latter by filtration.

The most recent method of treating diphtheria is by inoculation with the serum of a horse that has been previously inoculated with diphtheritic poison. A large number of remedies had been from time to time proposed for the treatment of diphtheria, but without producing much effect on the general symptoms of the disease; and whenever a new therapeutic remedy is introduced it is necessary to study it carefully and watch it with the utmost attention. The employment of antitoxin in the treatment of diphtheria is based on the study of the pathology of the disease, which is an inflammatory condition of the mucous membrane of the mouth and air-passages excited by a special bacillus which gives rise to nerve degeneration. It is not the bacillus that induces the death of the patient, but the degeneration of the nerves, the chief symptoms being suppression of urine and a fatty degeneration of the muscular fibres of the heart. A single dose of the poison will give rise to the disease, and the fluidity of the blood is affected if this dose be a large one, but it is the absorption of repeated small doses of the poison during the course of the disease that has such a disastrous effect.

Two rabbits were experimented with. In one a dose of unmixed poison was injected, and in the other a mixture of poison and antitoxin. On examination after death, the former was found to have fatty degeneration of the muscular fibres of the heart and nervous degeneration, but the second rabbit had a perfectly sound heart and only a trace of nerve degeneration. Experiments have proved that antitoxin is quite innocuous, but the toxin induces paralysis on the fourth day after its introduction into the system of the animal.

Cardiac syncope in diphtheritic disease is due to the fatty degeneration of the muscular fibres of the heart.

In reply to a question Dr. Martin stated that the normal temperature of a healthy rabbit was 103° F., and to another he said that not only was the injection of antitoxin followed by no inconvenience to the animal, but that the latter even increased rapidly in weight.

DR. G. SIMS WOODHEAD stated that the persistence of the local exudation indicated a severe form of diphtheria, and that when it was gelatinous the case became a very grave one indeed. The symptoms were albuminuria, sometimes but not always pyrexia (occasionally there was no elevation of temperature), and drowsiness; vomiting was of frequent occurrence, as was also suppression of urine; when the renal secretion continued to pass it was much more concentrated than usual; there was also more or less hemorrhage from the mucous membrane, and dropsy. If convulsions supervened they were the immediate precursors of death. Some of these aggravations of diphtheria, especially the last, have been attributed to the use of antitoxin, but, the speaker considered, without adequate reason. In some cases the diphtheritic bacillus could not be detected, and in such cases the injection of the antitoxin was productive of no effect.

In 241 cases of diphtheria 105 were treated with antitoxin and 136 by other methods, and the mortality in the latter was considerably higher than in the former. Age was an important factor and the older patients were found to do better without the antitoxin; nevertheless, a general consideration of all the facts tends to prove that the antitoxin treatment of diphtheria is one to be commended and followed.

The antitoxin does not cause any diminution of the albumin in the urine, nor does it influence the anuria; but in cases where it was used there was found to be a larger proportion of paralytic complications than in those cases where it had not been employed, although it must not be too hastily concluded that the paralysis is the actual result of the use of antitoxin. Paralysis is usual after severe cases and infrequent after those that are of a milder type, and many of the former would probably have succumbed had they not been tided over the peril by the antitoxin. Where antitoxin was used in mild cases, no paralysis was observed. The fact is that the antitoxin has no control over the paralysis, which, however, is never permanent, and from the effects of which no deaths have been recorded. Antitoxin, in like manner, does not influence glandular enlargements or broncho-pneumonia.

In all cases it is important to commence using the antitoxin as early as possible, but there is no benefit to be derived from other concurrent treatment. In complicated cases not much can be hoped for from its employment. About the worst combination of diseases is that of diphtheria and measles, which nearly always ends fatally from broncho-pneumonia.

Diphtheria varies in severity in different years, in some being of a much more serious type than in others, and although the results of the antitoxin treatment have been less favorable in the former, enough encouragement has been obtained all round to induce the speaker to persevere with it.

DR. ALEXANDER JOHNSTON mentioned the occur-

rence of paralysis of the soft palate, a subnormal temperature, diminution of urine, and vomiting as being of frequent occurrence in diphtheria, and said that the diagnosis of the disease was established by bacteriological examination, notwithstanding the fact that other micro-organisms were found along with the diphtheria bacillus. He had used antitoxin in some cases which turned out to be scarlet fever, and they were uninfluenced by it in any way. In the Belvedere Hospital, Glasgow, the highest mortality was 41.4 and the lowest 28.63 per cent.; he tried the antitoxin in 7 cases, 5 of whom died, and the other 2 derived no benefit.

Dr. von Ranke said that he began the use of antitoxin nine months ago, but he only treated cases of pure diphtheria, all very severe cases, the mortality being 17.7; 28.4 per cent. of his cases were treated by incubation and 41.1 by tracheotomy. In only three cases did he have to retain the tube longer than four days; he always has it removed every day for a little while to see how the patients get on without it.

In his cases of diphtheria of the pharynx only two per cent. died, and they succumbed to heart failure; nineteen per cent. had septic symptoms. The mortality varied according to the age of the patients. Under twelve months all died; between one and two years 27.5 per cent. Before he began the use of the serum treatment the average mortality was forty-six per cent., the highest, 57.7 per cent. Since he had used the serum it was 17.7 per cent., and the change in the clinical course of the disease was also very marked. Before, it was progressive. Laryngeal stenosis was benefited in a special manner. Croup cases improved in the most wonderful way, and twelve hours after admission no operation was necessary; if the little patients were intubated the tube could be removed much earlier than would otherwise have been possible without the serum treatment. If antitoxin was not a specific in diphtheria, at least it was a most powerful remedy.

Dr. Lennox Browne was not altogether opposed to serum injections in diphtheria, but he was watching the treatment and had arrived at a very different conclusion from that of the last speaker. He thought that the importance of the rise and fall of the temperature has been over-estimated. Antitoxin had no influence over nephritis. It was said that the serum was only of use in cases of uncomplicated diphtheria, but others were inclined to believe it was beneficial in mixed cases also. Statistics, he thought, should not be too much insisted upon, as the records made were the result very frequently of only a small number of observations. Antitoxin and classical treatment contrasted showed much the same result. He did not think the reviews in the *British Medical Journal* had been fairly set forth. One case was counted twice over, and one was stated to have been treated on June 31st, a day he did not find on the calendar. Improvement under good hygienic conditions was certainly to be taken into account.

Dr. Baginsky, of Berlin, said that he had written a book about this method of treatment. Before the introduction of the serum treatment the mortality from diphtheria had been appalling. He began the use of antitoxin in March, 1894, prior to which time from forty-one to fifty-eight per cent. died; now the mortality was no more than fifteen per cent. and in the best class only five per cent. The whole character of the disease had been changed. True, they had still some cases of failure of the heart, but only in mixed cases that had come late under observation; probably had they been seen earlier these patients would have lived, for he had never lost one from cardiac complications when the case had been under his care from the commencement of the complaint. If some patients had nephritis it was not a recent development. The mortality of cases with laryngeal stenosis before the serum was introduced was sixty per cent., but only twenty-one per cent. since. He thought he had some little excuse for his enthusiam.

Dr. Sims Woodhead had got past the stage of enthusiasm that was untempered by facts. He thought some were too timid in their use of the antitoxin, for the best results were obtained from the largest doses, which were employed by those who had the greatest amount of experience with the serum. He was not prepared to find the mortality influenced in so marked a manner, but he had remarked upon the alteration in the character of the disease that had been mentioned.

Dr. H. M. Biggs, of New York, spoke from memory only, having no data within reach. He explained that any medical man in New York can obtain a supply of antitoxin free of charge on application to the Board of Health, and can have it administered, if desired, by a medical inspector. The mortality had been very considerably reduced as regards both private and hospital cases. The antitoxin conferred a remarkable immunity.

Diphtheria broke out in four institutions for children in New York. There were 107 cases in all. Then the rest of the children were inoculated with the serum, and after that only three more cases occurred. The immunization, however, only lasts for about a month, and then the inoculation has to be performed again; but in all probability a few successive inoculations would ultimately confer permanent immunity. He could not speak too highly of the treatment by antitoxin. No bad results followed, except a slight and temporary urticaria in a few instances, and a trifling rise of temperature for four or five hours.

Dr. Campbell Hall had not much to add to the discussion; nevertheless he came from a place where diphtheria was endemic, and he began the serum treatment as an unbeliever, but was surprised with the result. In not a single instance did the membrane spread after inoculation, and he would not now think of treating the disease in any other way than with antitoxin.

Operative Treatment of Athetosis. — Dr. C. E. Beevor then read a paper, the joint work of himself and Mr. Horsley, "On the Pathology of Severe Athetosis." The first patient operated on had suffered from an incessant, uncontrollable movement of the hand and arm, but after the removal of a portion of the cortes cerebri there was complete paralysis of the affected arm lasting for a year, when motion began to be gradually restored. Then the man "had a bad turn" and eventually died, having been relieved by the operation for a period of a year. The athetosis in this case was the result of injury through a fall on the head.

In the second case the athetosis was also the consequence of an injury, and the relief was complete for two years, when, owing to hernia cerebri occurring through the necrosis of the bone graft, meningitis set in, the inflammation became general, and the patient died.

Before trephining in these cases numerous experiments had been made on monkeys and on an orang-outang.

The Thyroid Treatment of Myxœdema. — Dr. George R. Murray, of Newcastle-on-Tyne, read a paper entitled "Notes on the Progress and Present Condition of the First Case of Myxœdema Treated by Thyroid Extract."

The question had been asked if this was a complaint that was capable of being cured, to which he would reply that it was, and that it would not return when the remedy had been discontinued. Myxœdema is a disease of the thyroid gland, but even when the gland cannot be restored the patient can be cured, and there will be no return of the disease as long as he continues to take the remedy in daily doses of ten grains each.

Dr. Colin Campbell mentioned a case in which a relapse had taken place and all the symptoms of myxœdema had returned after a shock caused by a railway accident; but the patient had ceased taking the extract

four months before, as she considered that she was completely cured.

Dr. Murray, in reply, said that he doubted very much whether the railway accident had had anything to do with the return of the symptoms, for a relapse might be expected in about one hundred days after a patient had given up the daily dose of the extract.

Uranium Nitrate in Diabetes Mellitus.—Dr. Samuel West said that in large doses this salt acted as an irritant poison, and small doses interfered with the digestion of starch and albumin. A knowledge of this action had induced a homœopathic physician to try the drug on a patient suffering from diabetes. Dr. West first tried it on some out-patients who were suffering from that disease, and they informed him that after taking it for a short time their secretion of urine was diminished by about half. The uranium nitrate was then administered to some other patients more favorably situated than the first. He began with small doses of one grain, gradually increased to twenty grains three times a day, and the effect was most marked, for not only was the output of urine greatly diminished, but the quantity of sugar contained in it was also correspondingly decreased, the excessive discharge of both sugar and urine returning as soon as the drug was stopped. This certainly proved its restraining power.

Another case that had hitherto been treated by a strict attention to diet was then put under the uranium nitrate treatment, with the effect that the urine was much diminished in quantity, but as the drug caused nausea it had to be discontinued, and then the diabetic symptoms at once returned. It was now cautiously resumed, and for four or five months this patient's urine was normal in quantity and absolutely free from sugar. The patient then had an attack of influenza, when the uranium was discontinued and the patient soon relapsed into her former condition.

Several other cases also derived great benefit from the use of the uranium salt. The drug does not, however, cure the disease, but it certainly exerts a very marked effect upon its progress.

When the minimum secretion of sugar has been reached the dose of the drug may be gradually lessened, even down to one grain a day, without a return of the symptoms, but it had better not be left off altogether.

Dr. Garrett-Anderson wished to know if uranium nitrate was an expensive drug, and also what effect it had on the diabetes of children.

Dr. West replied that he did not know the exact cost of the drug, but he imagined it was by no means an expensive one. He had never tried it on a child.

Bronzed Diabetes.—Dr. Hanot then gave a short address in French, entitled "Notes sur le Diabète Bronzé." He began by apologizing for speaking in French, but his knowledge of the English tongue was too limited for him to venture to use it. The essential character of this disease, for he considered that bronzed diabetes was a special and independent malady, was the deposition of pigment not only in the liver, but in every organ of the body. This deposition was not an effect of the diabetes, but was due to an obscure common cause; it differed in many essential points from morbus Addisonii, especially in the bronzed or pigmented condition of the mouth and fauces. It was certainly a disease *sui generis*, and terminated rapidly in the death of the patient. He had seen seventeen cases of bronzed diabetes, in all of which there was a large concretion of sugar. The final complication was generally pneumonia, but occasionally the patient succumbed to mere exhaustion or to syncope.

Direct Intra-pulmonary Medication.—Mr. Colin Campbell said that the lungs were possessed of great absorbent power, perhaps as much as the intestinal tract itself, and much greater than that of the latter in many diseased conditions. Therefore he considered that direct treatment of diseases of the lungs would be found to have a great future before it. At present the only mode of directly medicating the lungs was by means of the inhalation of vapors, but it was more than doubtful whether the latter reached the ultimate ramifications of the bronchi, and if creosote, for instance, could be introduced directly and brought into immediate contact with the pulmonary tissue, much more good might be expected from its employment.

The complaints most amenable to treatment by this method were all bronchial affections, asthma, tuberculosis, and similar morbid conditions of the lungs; in chronic bronchial asthma it had a marked beneficial effect.

Considering the *rationale* of the treatment, it might be expected to do good in cases of chronic interstitial pneumonia, but the result was somewhat disappointing. In hemorrhage from the lungs, however, the direct injection of a mixture of glycerine and turpentine was productive of benefit, and was followed by no bad results, or even by inconvenience; even in cases where a cure is impossible, it will afford great relief. He had known cases of hereditary phthisis presenting large cavernous abscesses in the lungs to be entirely and permanently cured. At first there might be a little difficulty in practising these intra-pulmonary injections, but what operation was not attended with more or less difficulty when first practised? The difficulty, however, is soon overcome and the operation is performed as easily as the passing of a catheter or the administration of an enema.

Dr. Murray bore testimony to the efficacy of the treatment in several cases of pulmonary affections, but he had not employed it in tuberculosis.

In reply to a question Mr. Colin Campbell said that he had a special syringe made for practising these injections. It was longer than those in ordinary use and had a more extended curve. He used turpentine in equal proportion with olive-oil, and in the interval between the acts of inspiration and expiration he injected one hundred minims three times into the lung, which he had found was as much as was required. The administration was productive of so little inconvenience that no patient had ever objected to a repetition of the injection. He found that a mixture of olive-oil and menthol recommended by Sir T. Grainger Stewart did not mix with the sputum, and had substituted glycerine for the former, which mingled freely and carried the menthol along with it, rendering the act of expectoration easy by liquefying the viscid sputum. He had never found that dypnœa was produced, and should not think it would be twice in ten thousand cases. Of course it required practice to give the injection in the right way, but a little experience would soon enable this to be done with complete satisfaction to the patient.

Second Day, Thursday, August 1st.

Discussion on Acute Lobar Pneumonia.—After some preliminary remarks by the President of the Section (Dr. Pavy), Dr. Douglas Powell opened the discussion by observing that we are on the border-land of a new method of treating this formidable disease, the death-rate of which still holds its own. To describe the well-known symptoms of pneumonia would, he thought, be a waste of time, while its etiology has exercised the minds of physicians from all time. The disease bears no proportion to the inclemency of a climate, but in the temperate zones it is more prevalent during seasons of low temperature, the months of January, February, and March having the highest proportions, both as regards the incidence of pneumonia and its mortality. Among other conditions favorable to the development of the disease are personal imprudence, exposure to atmospheric effects in exposed places, insufficient or inappropriate clothing, the artificial conditions of social life, sudden changes of temperature, which are all to be taken into consideration when estimating the etiology

of pneumonia. It has been said that he is a contemptible man who is always absorbed in the contemplation of his own skin; but an imprudent man who takes no notice of his surroundings is not much more to be commended.

With regard to an etiology depending solely on the entrance of a micro-organism into the system, such an assumption would certainly have a tendency to give rise to carelessness; we always have organisms with us, and they will do us no harm unless we furnish them with an occasion for destructive development.

The compensatory powers of the system may be defeated by nervous shock and imprudence, for nasal catarrh is unquestionably due to a surface chill, and of all the ills that flesh is heir to it is decidedly one of the most contagious, running its course rapidly through a household when one of the members has been attacked.

When pneumonia occurs in the course of a febrile disease, it does not arise during the period of active pyrexia, but when the temperature has begun to decline. With regard to pneumonia being caused by a special organism, the disease is a general rather than a local one, and its manifestation in a given locality is only part of its general presence in the system. Rheumatism is not favorable to the development of pneumonia. There are three favorite candidates for the honor of distributing pneumonia among us; the coccus that is found at all times in the saliva is the one that occurs most freely in cases of this disease; but, on the other hand, it is also found to exist in other diseases that are not quite analogous with pneumonia.

Osler did not find the pneumo-micro-organism constant, but observed others in different cases, and the pneumococcus exists largely in healthy saliva. Impaired vitality is an exciting cause of the disease.

Pythogenic pneumonia is practically the same affection as ordinary pneumonia, but the temperature is more fluctuating. When pneumonia spreads among the members of a household the probability is that they contract it from the same originating cause, and not through contagion. How far this cause is associated with the effects of sewer-gas is undetermined.

With regard to the treatment, the speaker's experience justified the routine employment of salines, diet, rest in airy room with a medium temperature of 60° F., but he preferred the dose of medicine to be given every six rather than every four hours, so as to allow more time for the administration of nutriment, and of more powerful drugs when these were indicated by the general symptoms. Quinine was far preferable to the old method of blood-letting and antimony, which were powerful depressants, and weakened the heart at the critical moment of the struggle. Tincture of iron was a valuable aid.

Pyrexia is a normal condition of pneumonia and is present in most cases; it is inimical to the development of microbes, and in interfering with it too much there is a risk of their increased action. But if the temperature of the patient rises above 104° F., it had better be reduced. The cold cradle is useful for this purpose, as are the antipyretics, but care must be taken not to let the temperature fall below the normal.

The consideration of pain in pneumonia is a most important one. Poultices, hot or cold, have but little effect in reducing it, but the use of ice-compresses is a vexed question at present. They are of decided advantage in the case of children and young adults, they do no harm, and as a rule relieve the pain, but have no effect on the respiration, and on the whole leeches are more reliable than ice for dispersing pain. Blisters of small size, followed by a rapid succession of hot poultices, are often useful, but the employment of morphine is of less decided advantage, as it certainly checks the secretions. When there is a tendency to cyanosis the inhalation of oxygen is productive of much benefit. Strychnine and caffeine are two powerful remedies, and the latter is the less dangerous, requires less supervision than the former, but is less potent. It should be administered subcutaneously, for the stomach cannot be depended upon to act, and when the patient recovers he may find himself confronted with an accumulation of the drug in poisonous quantity. Oxygen must not be reserved for a last resource, but be given as a cardiac tonic at an early stage to supply the left cavity of the heart with a sufficiency of red blood and sweep away the products of imperfect combustion.

Plethoric people are often carried off rapidly by an attack of pneumonia—overwhelmed by it, so to speak—and in such case leeches are indicated. On the fifth day of the disease acids should be substituted for salines.

The antitoxin treatment of pneumonia by the introduction into the veins of a patient of blood drawn from a convalescent from the same disorder is not satisfactory for several reasons, but chiefly owing to the difficulty of obtaining what is wanted at the right moment, and the operation, moreover, is not free from danger.

Dr. Washbourn was of the opinion that pneumonia was due to a coccus and to that alone. The inflammation had a tendency to spread, but was susceptible of being localized. The micro-organisms (pneumococci) spread through the walls of the alveoli. Both lobular and lobar pneumonia were due to a coccus, though its demonstration is difficult, for it dies out at a later stage of the disease, and is replaced by others.

Different animals evince a differing degree of susceptibility to the action of the pneumococcus; thus mice are peculiarly liable to its action, guinea-pigs less so, and fowls are immune.

The pathological changes observed are due to the action of a number of different factors, and the several micro-organisms give rise to modifications of the inflammatory process. Several varieties of the pneumococcus have been described, but they differ in appearance only. The pneumococcus produces fibrous pneumonia. The treatment of the disease by the injection of the blood of a convalescent is not difficult in the case of animals, and gives strong reason to believe that it will prove to be a specific for pneumonia.

Dr. Auld, of Glasgow, said that the inflammation of pneumonia was not confined to the lungs, but also spread to the meninges of the brain; the disease itself (pneumonia) was, however, a genuine inflammation due to the pneumococcus which circulated in the blood and produced or gave rise to a bacterial toxin. Leucocytosis diminished with the fall of temperature, and the local lesion in the lung was often a means of checking the general development of the micro-organism by preventing its expansion in other parts of the system. He agreed with Dr. Douglas Powell that pneumonia is due to the action of a special coccus. Pleurisy, though often associated with pneumonia, is nevertheless a distinct disease, for some rabbits he had inoculated with pleuritic serum developed pleurisy but not pneumonia.

The toxic crisis might be determined by the elaboration of antitoxin, but this was no sign that the disease was arrested or even diminished.

Dr. Dreschfeld, of Manchester, said that he would be practical in his remarks. The pneumococcus was the cause of pneumonia, and low vitality favored its development. The sputa should be carefully disinfected. Wandering pneumonia was similar to typhoid, the sputa were not sanguineous and the bacilli were not to be mistaken for pneumococci, but were more like the bacilli of influenza.

Dr. J. E. Pollock would rather add to his knowledge than discuss doubtful points. What was the meaning of pneumonia; what its cause and treatment? A micro-organism had been detected in croupous pneumonia, but it was also found in other diseases. What was to be inferred from that? Again, was it the cause or the result of morbid action? Certainly there are

many cases of the disease in which it is impossible to trace the action of a microbe. For instance, a robust man of thirty-five, who had always been healthy and temperate, without the least tendency to the disease, drove seven miles in an open trap in the face of a keen east wind. He was lightly clad, took a chill, developed pneumonia, and in spite of every care and attention died in a few days. Was this the result of the invasion of his system by a microbe, or was it due to the effects of a chill? We live in a world of microbes. The speaker then instanced himself as having been a resident physician in a hospital for phthisis without contracting the complaint, although he was not without a hereditary bias, as his mother had died from that complaint. Cause and effect are by no means invariable. Can phthisis be accounted for in every case by the microbe theory? He thought not; but if so it was contagious and our consumptives ought to be labelled "dangerous." Very well, but do not forget that theory is not proof, and must give way to clinical experience; laboratary knowledge by itself must be looked upon with caution.

Dr. Foswell, of Birmingham, considered that pneumonia was a constitutional disease which attacks other parts of the body as well as the lungs, and sometimes the inflammation of the latter organ is quite a minor part of the complaint; wherefrom the question arose, should it always receive the same name? In fatal pleuro-pneumonia there was always suppuration, but the presence or absence of that complication depended on the tissues involved. It is advisable to take the widest view of every case. The speaker once lost a patient who had enteritis as well as pneumonia because he took cognizance only of the latter.

Ice-packing is a valuable method of combating the effects of pneumonia, particularly in the case of children; after half an hour, sleep is induced and pain relieved, but if the latter has not disappeared by that time then a blister, or preferably a couple of leeches, should be had recourse to. Strychnine is valuable in cases with cardiac complications and should be administered subcutaneously. He had never observed any bad effect from its use.

Dr. Tyson, of Folkestone, could not hope to say anything new about pneumonia, but he differed on some points from several previous speakers, being compelled so to do by his own clinical experience. The time had come, he thought, when the word pneumonia, as significative of a distinct disease, could no longer be used by itself, but must be coupled with a differentiating adjective; thus, asthmatic pneumonia, inflammatory pneumonia, alcoholic pneumonia, septic pneumonia, which all differed, and must be taken, each on its merits. Country practitioners, as a rule, cannot undertake the study of bacteriology, and the treatment useful in each class or type of the disease is not the same, so that the laboratory student must work in conjunction with the clinical observer.

Dr. G. W. Balfour, of Edinburgh, had a theory of his own. No disease had ever been so diversely treated as pneumonia. Blood-letting, antimony, phosphorus, alcohol, etc., had each in turn been lauded as a panacea, and it was just the same to-day, new specifics for the cure of the disease were being announced every week in the medical journals. He was strongly of the opinion that treatment has little or no effect on the course of pneumonia, in which there is a tendency to recovery, and that the part of the physician is rather to obviate death than to control the course of the disease. Death, when it occurs during the progress of an attack, is always due to cardiac failure. No treatment can nullify exhaustion or prevent disease, but we must not aggravate either. Two grave features of the disease are to be guarded against, rise of temperature and consolidation of the lung tissue, while exudation in the pulmonary centre is not worse than it is anywhere else, the heart takes little notice of the apparent obstacle. A very high temperature is productive of exhaustion and indicates complications.

The more powerful antipyretics each possess a danger of their own, but digitalis is eminently useful along with free stimulation. The recumbent position should be strictly enforced, and the digitalis must not be pushed too far. Too much trust should not be reposed in opium, but chloroform is possessed of valuable remedial power; pain is vanquished, cough allayed, temperature dropped under its use, but it must be carefully watched and its administration in small doses by the mouth, in some convenient emulsion, is preferable to inhalation; it can be conveniently replaced by chloral, which is at once an antipyretic, an hypnotic, and eminently manageable.

Dr. Baümler, of Freiburg, preferred the treatment of pneumonia by the cooling method—cold-cradle, ice-packing, both of 70° F., all of which assisted nature by causing the external blood-vessels to contract and a flow of blood to pass through and "flush" the internal organs; but a patient with a fatty heart requires a different course of treatment. The kidneys, especially, are benefited, for the cold excites their action, and without it the urine becomes concentrated, but with the cool method it flows freely and many injurious products are carried out of the system, strength is saved, and a restless, wakeful brain receives rest and quiet. This is especially noticeable in the case of children. Where there have been convulsions, these disappear after the cold bath, owing to the beneficial effect of the latter on the extremities of the sensitive nerves in the skin. To sum up the matter, the general effect on the whole course of the disease is great. Treatment should not be wholly symptomatic, as could be easily proved, but the speaker had not had time to prepare statistics. He had used antipyretic medicaments, but had latterly come to the conclusion that cooling measures are infinitely preferable, owing to their direct action on the circulation and the various organs. So many differing causes affect the progress of a case of pneumonia that it is not always possible to estimate the issue, and much depends on the remnants of previous disease in the lung.

Dr. Clifford Allbutt agreed with Dr. Pollock that if a bacteriologist said that a certain microbe was the cause of the disease he should be put down, but he doubted that anyone had ever said so. He thought the disease could not be traced to chill alone or to bacteria alone. Leucocytosis was a marked means of differentiation between the different forms of pneumonia. If cold water depresses the enemies more than the defenders of the citadel of life, well and good; but to the speaker it seemed to cut both ways. The inhalation of oxygen was most valuable. He had seen a patient kept alive by it for six weeks, and it alone had kept off cyanosis and death as long as it was possible for anything to have done so. Superinfection was due to the spreading of the original toxin, and in such cases the ordinary tincture of iron was of great benefit. Bleeding produced a temporary effect in acute pneumonia, but only a temporary one.

Dr. G. A. Gibson, of Edinburgh, agreed with Dr. Clifford Allbutt as to leucocytosis and the part it played during the progress of pneumonia, and thought that Dr. Pollock misunderstood the question of bacteriology. How was it that the clinician never found out by his observations at the bedside that cholera was propagated by a bacterium that lurks in water?

Dr. Sinclair Cochill, of Ventnor, thought that croupous pneumonia was the gravest type of the disease, and preferred laudanum to morphine in treating it. Aconite lowered the temperature, and sponging with tepid or cold water was also beneficial, especially if the former was mixed with a large proportion of eau-de-cologne.

Dr. Hawkins, of Reading, considered that pneumonia is an infectious disease that deranged many

physiological functions, of which one result, consolidation, might persist for a considerable time. Injury might give rise to pneumonia. He considered strychnine to be useful in the treatment of the disease.

Dr. Lees thought it was most important to give the patient sleep first of all, but by means that would not cause subsequent depression. He deprecated venesection, and thought with regard to cooling measures that the use of the ice-bag was preferable to the bath, but reducing the temperature of the patient was not very important. When the ice-bag failed to give relief it was owing to timidity on the part of the physician. He instanced as a parallel case the all but instantaneous relief in acute sciatica from the use of the ice-bag.

The microbic origin of pneumonia was bar to the treatment of the disease by the ice-bag, for the pneumococcus had been shown to be extremely susceptible to changes of environment. In the case of children it was requisite to apply bottles of hot water to the feet in order to keep up the temperature of the extremities and of the abdomen; but if there was the least tendency to cyanosis the ice should be at once discontinued.

A subnormal temperature was not opposed to the ice-bag treatment, by the adoption of which, the speaker affirmed, some cases under his care were much benefited.

Dr. Pope, of Leicester, was of the opinion that the pneumonia developed during the course of an attack of typhoid fever was distinctly infectious, and recommended the immediate isolation of a patient showing symptoms of it in a fever ward, otherwise the other inmates would probably all become affected. He had seen much benefit result from the admixture of spiritus ætheris nitrosi with the usual salines, and had found that sodium nitrate was no adequate substitute for the more volatile preparations.

Dr. Shingleton Smith, of Clifton, had been informed that gigantic doses of digitalis had been followed by the most beneficial results at Bucharest, and hoped that should he ever contract the complaint that Dr. Powell would not evince any timidity in prescribing it.

Dr. Squire objected to the term "croupous," being applied to the pneumonia of children, and had seen as good results follow the ordinary treatment of the disease as were said to come from the use of the ice-bag, if not, indeed, better.

Dr. Douglas Powell, in reply, was much gratified by the discussion that had taken place upon his paper, and was of opinion that the use of antitoxin was the line that must ultimately be followed in the treatment of pneumonia. Oxygen was undoubtedly a valuable cardiac stimulant in grave cases, but he was reluctant to apply blisters to a child; in the case of children slight counter-irritation was preferable.

Leucocytosis was one of Nature's methods for getting rid of the disease. As to the mode of treatment in vogue at Bucharest, where such excellent results were obtained from the use of heroic doses of digitalis, he had been informed by Professor Baümler, who was sitting beside him while Dr. Smith spoke, that the patients were all strong, vigorous young men, soldiers, in the prime of life.

He did not attach much importance to the use of spirits of nitrous ether in consequence of its action on the skin, but it certainly was of benefit in promoting the excretion of urine.

Guaiacol in Tuberculosis.—Dr. Sinclair Coghill, of Ventnor, then read a paper on "The Hypodermic Use of Guaiacol in Acute Pulmonary Tuberculosis." Guaiacol, he said, was obtained by distillation from creosote, and was administered to the patient by inhalation. His experience with the drug in these cases was most encouraging. When it was given subcutaneously, the buttock was the most favorable region for the injection.

Serotherapy of Tuberculosis.—Dr. Maragliano, of Genoa, presented a paper, which was read by the Secretary, on the treatment of pulmonary tuberculosis by specific serum.

It is impossible to argue from an effect upon one animal to another. When the tuberculin has been injected into a tuberculous patient, the latter experiences a sensation of well-being that is not produced by any other treatment; by degrees the characteristic bacillus disappears from the blood, and from being acute the symptoms become slight, but there is no instance as yet of complete recovery from the disease. Is no benefit derived? Yes, providing the treatment is prolonged sufficiently; but where destructive centres exist the complaint will break out again and again, and a perfect cure cannot be hoped for. Fever has an unfortunate influence on the result. Hæmoptysis does not counter-indicate the employment of tuberculin, and any part of the body that may be most convenient may be selected for the purpose of injecting the remedy, as no reaction follows.

Dr. J. E. Squire said that naturally the association of the disease with bacilli had given rise to an attempt to destroy the latter *in situ*, but he questioned whether it was possible to do so. We cannot reach the microbes in their retreats, and if we could we could not introduce a sufficient quantity of the antidote without endangering the safety of their host, and so the bacilli will be only scotched, not killed. Drugs have their value in the treatment of phthisis; they prevent secondary infection by destroying the bacilli that have been ejected from the system. He preferred the use of inhalations to the dosing of the patient by the mouth, but hygiene was better than antiseptics, while good food and good fresh air were superior to every other remedial agent that had been or could be devised. The strengthening of the tissues might be lost sight of in a vain attempt to kill an offending bacillus. If inhalations were employed, they must be used freely, as half-measures only defeated their own object.

Third Day, Friday, August 2d.

The Causes of Acute Rheumatism and its Relation to Other Affections.—Dr. W. B. Cheadle said that he used the term acute rheumatism in a strict sense, as implying a disease in which were manifested pericarditis, endocarditis, and rheumatic joints. Endocarditis had seldom any other exciting cause, a possible exception being in the case of chorea, which, however, was intimately associated with a history of rheumatism, as were also its pathological associations, so that where endocarditis was found in a case of chorea, the latter was rheumatic in its origin. Pericarditis also had a rheumatic origin and might be associated with endocarditis in the same subject, but might occur alone.

Tonsillitis was a disease of debility often associated with the rheumatic diathesis as well as with arthritis, and the erythemata had a similar connection, so had purpura. The erythema might occur in any part of the rheumatic series. Fatal chorea resulted from extravasation of blood, and in cases of scarlet fever that ended fatally endocarditis was always present, showing the close relationship of this disease as well as of chorea to acute rheumatism.

Chorea, whether alone or associated with endocarditis, might be followed by arthritis, and occurred in families in which rheumatism was ripe. He instanced the case of a patient who had chorea only, like her mother, but the grandmother had suffered from rheumatism. Statistics, however, were imperfect and unsatisfactory, rheumatic arthritis in children being often slight and evanescent.

False chorea, affecting the face but not the limbs, was more common in boys and presented a good deal of analogy with stammering; in such cases there were no

rheumatic manifestations. In fifty cases of chorea that he had collected, there was history of family rheumatism in fifty-two per cent., and including erythema, sixty-five per cent. Chorea resembled rheumatism in its liability to relapse and might occur in any part of the rheumatic series, and in the majority of cases there would be a history of acute rheumatism.

In rheumatism complicating scarlet fever there might be pericarditis or endocarditis, or both, also erythema nodosum, articular rheumatism, pneumonia, bronchitis, though the position of each in the series was uncertain, and such was the Protean character of rheumatism that they might all arise separately and independently of each other. In a case of bronchial catarrh where the heart was affected without any other symptom of rheumatism, the patient, a child, developed chorea a few months afterward, in nine months more acute rheumatism, and in a year both.

The rheumatism of childhood differs in many respects from that of adult life. While age increased the tendency to affections of the joints, it had a contrary effect upon those of the nervous system. Chorea was an affection of childhood and at that age arthritis was at its minimum, but with the progress of years the position was reversed. In adults, arthritis was the most ordinary complication, but in childhood the tendency to it was only slight.

Diversity of opinion prevails as to the etiology of the disease. Was there a morbid agent? What was the effect of surroundings, of age, of sex, of constitutional proclivity? An external factor was chill, which was often invoked without reason but must in rheumatism be allowed. A boy fell into a stream, but stood about in his wet clothes, for fear of incurring reproof or punishment, until they became dried upon him, and this imprudence on his part was quickly followed by an attack of acute rheumatism, so that the relation of cause and effect admits here of little doubt.

Acute rheumatism is a disease of temperate climates, in which chill is a common but not an invariable factor; seasonal influences are important, the disease prevailing more in winter and spring than in summer and autumn. Acute rheumatism, however, often occurs in dry seasons when the ground is hot, but this is by no means incompatible with the theory of causation by chill, for prolonged bodily exertion in hot weather not only weakens the system, but is not infrequently followed by a rapid lowering of the body temperature—in a word, chill—and where there exists a constitutional tendency the disease is very apt, under such circumstances, to develop itself.

Parents of the better class know all about their children and their ailments, but there is usually a defective history in the great majority of the cases brought to our notice. Where there is a double inheritance, that is, where there is a rheumatic tendency in both parents, we find the most striking instances of acute rheumatism. A girl of nine had a severe attack of chorea with endocarditis and pericarditis, and subcutaneous nodules, and she ultimately died from cardiac dilatation. Her family history was charged with rheumatism on both sides.

The most potent influences are chill, bodily fatigue, a dry season, and constitutional proclivity. Is the *materies morbi* a simple chemical product, or a micro-organism, or an irritation of nerve extremities by chill? We have no proof that endocarditis and pericarditis are due to any other factors.

Gout and rheumatic arthritis have no relationship to each other, and when pericarditis supervenes in the course of the former disease it is referable to Bright's disease and not to rheumatic toxæmia.

Lactic acid and uric acid have been suggested as the toxic agents in acute rheumatism, but the theory is one that is difficult of acceptance, for we have no evidence of the presence of either. Clinical observation is opposed to the idea of any relationship between gout and acute rheumatism; the diseases occur in different classes of patients.

The theory of microbic origin has analogy in its favor, but on the other hand acute rheumatism is not communicable from one person to another, nor is it malarial in its origin, but is directly excited by a sudden chill; one attack leads on to another, as in the case of influenza. True, family proclivity does not directly militate against the microbic theory of the origin of acute rheumatism. Cases of the transmission of the disease are rare and by no means indisputable. No organism peculiar to the complaint has been identified, nor does the disease spread by inoculation, so that on the whole we are bound to maintain an open mind and admit that the direct cause of acute rheumatism has not yet been determined.

Sir Dyce Duckworth had been much impressed by the ability and lucidity of the paper, to which he had listened with as much profit as pleasure, and he was guilty of no exaggeration when he termed it a masterpiece. The subject of rheumatism was one that had much interest for him, but it was not a simple subject. On the contrary, he might say that there were many rheumatisms. It was not merely a disease of the joints. There must be predisposition to the disease which must have a basis. Low vitality, exhaustion, chill, shock, and predisposition made an individual the prey of an organism that had a power of generating toxin. True, no organism had yet been identified, but its existence was clearly indicated by analogy, and a low temperature favored the bacillary invasion; there was a tendency to relapse, new germs recurring when dieted with favored pabula. The infective theory certainly failed to explain all the phenomena. The theory of nervous causation and a hereditary diathesis undoubtedly assisted the work of the infecting agent; many persons present no such soil and never develop rheumatism, as some never contract tuberculosis, so that, on the whole, we must come round to the infective theory.

Dr. Archibald Garrad thought that rheumatic fever was a systemic disease, and not merely a local one confined to the joints. A momentary chill could not cause such an accumulation of lactic acid as to produce the disease, although it had been said by Sir W. Foster that a diabetic patient had developed acute rheumatism after taking large doses of lactic acid. The local manifestations of the disease are such as might be expected to occur from the invasion of a micro-organism, but the erythemata of acute rheumatism were not infective in the ordinary sense of the term. The disease had more analogy with those of undoubted malarial origin; but in that case how did chorea fit in? It bore the same relation to rheumatism that paralysis did to diphtheria. The specific poisoning might precede motor disturbance without other changes; there were no morbid alterations in chorea, and in acute rheumatism the temperature presented no definite curve, although when it affected certain serous membranes there was more disturbance, though endocarditis frequently produced no rise in the temperature.

Dr. Mantle thought the etiology of acute rheumatism was decidedly bacterial, and this view was acquired from observations at the bedside in localities which were devoid of sanitation, and there rheumatism was endemic, as well as scarlet fever and tonsillitis. He had seen five cases of scarlet fever in young people, and only for the rash would have put them down as acute rheumatism. Rheumatism occurred in two-thirds of all scarlatinal cases as part of the disease, and not as sequelæ. Endocarditis was common in scarlatina, but sweating was not. He had seen two cases of rheumatism and two of scarlet fever in the same house at the same time, which proved, he thought, the concurrence of the two, so-called, diseases. Erythema nodosum was seldom accompanied by rheumatic fever, and he rather looked upon it as the manifestation of a distinct

disease; it was occasionally associated with scarlet fever.

Tonsillitis and acute rheumatism had a subtle connection, and followed as well as preceded an epidemic of scarlet fever. Rheumatism was rarely infective, but sometimes it appeared to be transmitted from one person to another.

He had searched for a micro-organism in the serum, and always found a coccus in it as well as in the blood, and in all probability this was the cause of the disease; the toxin might be lactic acid produced by the action of the micro-organism in the system.

Dr. Newsholme objected to the term acute rheumatism being applied to rheumatic fever, for chronic rheumatism is not entitled to be called a distinct disease. Some years rheumatism is more prevalent than in others, and the epidemics occur at more or less regular intervals. In Norway, all cases of rheumatic fever are compulsorily notified. There is, however, no evidence to show that one person has ever been directly infected by another. It was thought that the greater or lesser abundance of the rainfall had an influence on these epidemics of acute fever, but they had occurred when the fall of rain was deficient. A dry subsoil and a high temperature favored the development of rheumatic fever.

Sir T. Grainger Stewart must suspend his judgment for the present with regard to the presence of a micro-organism in rheumatic fever, but admitted that the trend of opinion was in that direction. Various affections were included in the term rheumatic fever, and a differentiation of the different forms of the disease had become a necessity for the elaboration of a satisfactory plan of treatment. Rheumatism begins by being a local disease, and remains so for days before it infects the system generally. It originates in exposure to cold, the patient takes no notice, and after awhile other tissues than the one first affected are attacked; but if the local manifestation is taken in hand and proper remedies and precautions taken, the patient escapes; therefore, take warning by the first twinge and you will be rewarded.

Dr. Handford referred to the relation of endocarditis to rheumatism in children. He would not accept the theory of the bacillary origin of the disease. He had seen endocarditis where there was no affection of the joints, but the endocarditis may progress for weeks after all outward manifestations of the disease have subsided; which, he thought, was not reconcilable with the theory of bacillary origin.

Dr. Haig was an absolute radical in the matter of the etiology of rheumatic fever, and must plead the excuse of *audi alteram partem* in order to obtain a hearing. Rheumatism, in his opinion, was due to the introduction and retention of uric acid which was not formed in the body. Test the urine to discover uric acid, not the blood or the tissues, and form a right conclusion. Because no uric acid was found in the blood was not to be taken as a disproof of his theory; for if there was none, the reason was that it was all gathered into the joints and could not be in two places at once. The disease is due to this accumulation of uric acid in the joints; if it was in the blood there would be no rheumatism. In some cases salicylic acid has no effect, but that is because the blood is alkaline and has no relation to rheumatic fever.

Diet and drugs act on the rheumatic diathesis, for meat does harm by introducing uric acid and its salts into the body; cold and moisture favor its excretion from the blood and its deposition in the joints. Iron is objectionable, for the urate of iron is insoluble.

Dr. Stephen MacKenzie agreed with Dr. Cheadle that in the adult arthritis is the chief symptom of acute rheumatism, which, however, is not merely arthritis but a disseminated disease. The name rheumatic fever is not satisfactory, for sometimes no fever is to be demonstrated. The general tendency of the disease is in favor of microbic origin, but in the present state of our knowledge one must not commit oneself to it, although the absence of an organism is not a proof that the theory is not correct. Rheumatism may begin locally. Dr. Haig certainly had the courage of his opinion and a feeling of pity for all who did not agree with his view, which however carried no conviction to the speaker, for it is unsupported by facts. Its propounder appears to confound gout with rheumatism, if both are due to uric acid retained in the system. He remarked that some diseases did not frequently concur in the same subject. If a young person has rheumatism, a subsequent attack will be rheumatic also and not gout, and *vice versa*. If the supposed relationship really existed, then salicylic acid should have some effect in gout, but it had no influence at all upon that disease.
